June 18—Found the patient much improved in appearance, temperature 99, pulse 80, cheerful, no nervousness, though complained of tired feeling in the muscles of the jaws when the mouth was opened widely; had been gaping all through the day; could open the mouth widely and had eaten a good dinner.

June 19—Temperature normal, pulse 80, restless until twelve o'clock the night before and then slept well; appetite good; complained of some pain in the foot and leg.

June 20—Temperature 99, pulse 90, rested well the night before but complained of some stiffness in the jaws at times and other symptoms seemed to indicate a recurrence of the attack; she was given, therefore, the last third of the bottle of antitetanic serum; the symptoms gradually disappeared and she made a complete recovery and today shows no evidence of the attack.

Remarks: 1. The serum treatment offers the best chance for life in cases of tetanus: it should not be relied on entirely, however, but other remedies should be used when indicated. 2. The treatment should be used early, preferably as a prophylactic, and the dose should be repeated as soon as any unfavorable symptoms appear. 3. The antitetanic serum should be of the best quality, injected with an antitoxin syringe and under antiseptic precautions.

Yours fraternally,

MATTHEW M. SMITH, M. D.

The Bill was Disallowed.

CHICAGO, ILL., July 20, 1898.

To the Editor:—I wish to call your attention to two cases which will be of interest to the medical profession.

On March 25 I appeared before Judge Kohlsaat with a bill for \$25 for professional services against the estate of Byron A. Baldwin. My bill was for administering an anesthetic and assisting at an operation. The surgeon's bill, presented at the same time, was allowed after being cut down. My bill was taken up immediately afterward, when the judge delivered himself, in substance, as follows: Haven't I just allowed one doctor's bill against this estate? When one doctor is paid, they are all paid; I can't have half a dozen doctors coming here making claims against this estate. If you are entitled to anything you must look to the other doctor for it. The bill is not allowed.

The following is from the *Chicago Record* of July 12, 1898: "WINE BILLS ORDERED PAID.—The club dues and wine bills of John Borden Ketcham, over whose estate there was much litigation after his death last fall, were ordered paid by Judge Kohlsaat yesterday. Among the claimants who appeared with unsatisfied bills were the Washington Park Club, \$31; the Chicago Club, \$53; the Gardiner Commission Company, \$178, and the Bodega Wine Company, \$25."

From this, one is justified in inferring that the judge thinks it scarcely necessary that doctor bills should be paid, or that a man is not entitled to the services of more than one doctor at a time; and that wine bills are sacred, and that a man may patronize as many liquor dealers as he chooses. If the judge's ruling in this case is in accordance with the law, it behooves doctors to collect in advance for all consultations and for surgical operations, where more than one doctor is always required. But then the judge's office-boy knows that this is not law, but caprice.

Yours truly,

D. H. GALLOWAY, M.D.

200 Oakwood Boulevard.

Inebriates in the Army.

HARTFORD, CONN., July 20, 1898.

To the Editor:—I have received two very urgent letters for my opinion on what is asserted to be facts in relation to the appointment of several persons to very responsible positions in the army. It is said that these persons are moderate and periodic drinkers of spirits, who are frequently intoxicated, and I am requested to write an opinion of such persons and their disabilities for such service. I can not say anything of the individual cases mentioned, but the same business principles should prevail here as in civil life. The moderate or periodic drinker is not considered a safe man in positions of responsibility, no matter what his capacity may be otherwise. In the early days of the Civil War, a number of inebriates were in responsible positions on both sides, and some way sad disaster followed their bad judgment. In those days the delusion prevailed that alcohol was a real stimulant and tonic, and in times of great strain a valuable help. Some most bitter experiences disproved this, and the last years of the struggle found nearly all the leading officers in command total abstainers, at least those in active duty on the battle-field. The moderate drinkers, and the men who drank to give them force and

strength for great emergencies disappeared. They were put aside as dangerous men to depend upon. The facts are established beyond question, that no brain-worker can use alcohol to advantage in times of excitement and mental strain, and no inebriate is competent for emergencies of any kind. These facts are the result of constantly increasing experience in business circles, and their recognition is more and more prominent in every field of activity. An inebriate officer in the army is a very dangerous man, more so than an inebriate engineer on an express train. Talent and capacity is of little value compared with a clear brain and steady nerve. While it is possible that inebriates may secure responsible places in the army, it is almost absolutely certain that their disability will be recognized, and in times of great peril they will be found in subordinate places. A very capable officer was suddenly detached from active duty in the Civil War and placed in an unimportant position. He died with the impression that it was the jealousy of the commander that put him aside at this time, and wrote bitterly of this and other events. In reality he was an inebriate, who a short time before this event was widely delirious on the battle field. His superior officer was afraid to trust him, and the real reason was never mentioned. Service on the field and in the camp always sifts out the strong, capable men, and no officer can hope for promotion or eminence, who depends on alcohol for aid in the hour of trial. There was in all probability no better army than the one dissolved in 1865 at the close of the Civil War. The army of today is commanded very largely by the veterans of 1865, and it is safe to say that few, if any, alcoholic incapables will ever occupy responsible situations, at least very long. Such men may be in the service, but their incapacity will certainly find them out.

T. D. CROTHERS, M.D.

Human Serum in Yellow Fever.

ATLANTA, GA.

To the Editor:—During the Yellow fever epidemic of 1897, while regretting that Sanarelli had not been able to put out his serum for the treatment of this disease, the thought occurred to me that the blood of a person having had the disease should answer all the purposes as well as the serum prepared by the tedious process through animals. It would be a simple matter to take blood from the vein of an immune, preferably one recently recovered from the disease, and immediately inject it into the patient affected or one to be protected. It would certainly be as safe as to use serum prepared through animals, which is bottled and kept some time before using, and I believe, would be fully as effective.

I made this suggestion to the Boards of Health of New Orleans, Mobile and Montgomery, but it was late in the epidemic and if it was tried I have not heard of it. A few days ago I wrote to Surgeon-General Sternberg suggesting that it be tried among our soldiers now exposed to such great danger from yellow fever in Cuba.

The success attained in the serum treatment of diphtheria certainly warrants hope for like results in other microbic diseases, and the method here suggested is applicable to them all.

C. C. STOCKARD, M.D.

Precocious Pregnancy.

PHILADELPHIA, July 19, 1898.

To the Editor:—In reference to your article of July 2, 1898, page 42, I recall a case in 1867 (of which I have notes) of the delivery of a girl ten days before she was twelve years of age. The confinement was normal, but was followed by a phlegmasia alba dolens in both legs. She had been brought up in a house of prostitution, and at the age of eight years had commenced cohabitation with boys. She menstruated at ten, and at the time of delivery, pelvis, mammae and pubic hair were well developed.

I was able afterward to confirm her statement. Her subsequent course was somewhat peculiar. After ten years of the most vicious profligacy she married a staid, quiet farmer, settled down to a life of intensely hard work, and after a number of syphilitic abortions, was so far cured that she raised a family of several children.

Very truly yours,

DE F. W.

Malaria Is Not a Disease.

NEW YORK, July 25, 1898.

To the Editor:—I note that in your items for your issue of the 16th inst. Dr. Koch is represented as speaking of "tropical malaria" as if the cause and effect were the same. That is to say, if my view is correct, malaria is a "bad air" or other bad influence that begets a certain disease, namely, malarial fever. I would like to ask you to turn to Dr. Koch's own writing in the *Deutsche Med. Woch.*, June 16, and tell your readers if he has fallen into the error of lumping cause and effect, or whether the *lapsus* has occurred in the course of transcribing his valuable observations into the English. By giving your readers a little light on this subject, you will, no doubt, confer a favor on others beside

Yours faithfully,

ZETA.

Appendicitis.

RICHMOND, IND.

To the Editor:—I am quite disposed to favor the writer of the article on "Appendicitis" in the *JOURNAL* of May 14, as I am perhaps the cause of several articles which have appeared in the *JOURNAL*. . . . Dr. Carstens has made the *amende honorable* in the same propositions, which I quote from his second article in the *JOURNAL* of February 19. Apropos, the London medical men are and have been laughing over the question of "What is Fame?" which was brought out by the indifferent regard to such names as Treves and Talamon, when such names are quoted with much gusto, as Price, Deaver, Murphy, Fowler, Morris and others. The last mentioned, as if aching for a controversy, thrust in his lance of the quill, hoping somebody would recognize him as the New York gladiator on this important topic.

First then to Dr. Carstens' propositions, viz.: 1. "He (Dr. Haughton) and I agree that a diagnosis should first be made." 2. "He (Dr. H.) and I agree that a convalescent patient should not be operated upon." 3. "He (Dr. H.) and I agree that patients absolutely recover without recurrence and without an operation." 4. "He and I agree that some patients need an operation, and if there is any difference in our views, it is simply when is the best time." So he says, "finally, after all, we are near together; there is no use in splitting hairs about it, and I am perfectly convinced that Dr. H. is a good fellow who means well and, what is more, is progressive and wants the truth." This is making the *amende* (?) all right as I took his first article. . . . This is what I expected the New York man would do, and so I have waited for him to define and commit himself, which he has quite fully done in the article, which I am about to review. I do not know Dr. Morris, but I shall attempt to pay my respects to him also in this squib, which would never have been written if he had not openly thrust in his lance in the Carstens' episode. I quite fully recognize the animus of New York surgeons toward western surgeons, and if any man will read his last article in the *JOURNAL*, and do it carefully and dispassionately he will come to the conclusion that he is arbitrary and dictatorial in tone in the assumption which is here quoted from the editorial of the *Texas Med. News*: "We feel that we are guilty of no exaggeration when we assert that such men, viz., men occupying extreme positions in every profession, and especially so in medicine and surgery." I am glad he put that in, as I may have occasion to use it before I am done. These men he refers to

is occupying extreme positions, are dangerous elements in the medical profession, a menace to the well being of society. The editor of the *Texas Med. News* is personating Dr. Morris, and goes further in saying that *such extreme radical teaching* by influential members of the profession, such as Dr. Morris, "is well calculated to do great injury." We quite agree with the Texas editor, and I am glad he comes to the front like a man and declares his convictions. Dr. Morris hence classifies himself in the category as radical, as distinguished from conservative. I had always believed that the truth is usually found midway between two extremes, and in this case I am betwixt and between. I am conservative when best and radical when best, and Dr. Morris can not do my thinking nor indicate in my cases what ought to be done. I fear it is too much the tendency of the younger surgical profession in the East to think for the entire profession. It ought to be remembered that some of us who live West, where broad prairies bound our vision and large rivers roll carrying our trade, and white-winged ocean birds of commerce infuse powers and dignity and "no pent-up Utica bounds our powers." It ought to be remembered also that some of us in the West sat upon seats of medical colleges in eastern cities and received instruction from the honored names who instructed the same men who now are at the front in surgery. It ought to be remembered also that some of the illustrious names who have been called to eastern schools and have aided the development of surgery, were men gathered from western fields. Sims, Gross and Parvin and others, have gone East to medical centers, and we have heard their teachings, and if this idea prevails in any large degree let it be understood that we upon western soil are *men* of large mould, and our institutions are developing them, the peers of any age or class.

I have nothing to say for myself except that having spent fifty years in college, hospital and general surgical work, and having taught surgery for fifteen years, I do not permit them to be more careful in diagnosis or in operative methods, and always reserve the right to adjudicate the situation if I am to be the operator. This is just what Dr. Morris does, only he is too radical; and all the knowledge of this question will not die with him.

I desire that these men, who are in positions to teach, should remember that he teaches best who teaches facts which can be utilized in the future. One fact is worth a thousand theories, and one life saved by any process which is best is a fact worth more to patients than all the theories of ages. So we go for the facts. We ask, is it so? Can you prove it? Besides, if you do or can, it is more convincing than to abuse men who dare to think, investigate and logically work out conclusions, and then go to the bedside and demonstrate them. I do not believe more than half I see, and very little of what I hear. I am more fully occupied with what I think along surgical and medical lines.

Appendicitis proper. Its medical and surgical relations.—I desire to notify all that I did not desire or intend to be drawn into any controversy, and made no attack upon anybody, but I am not disposed to be dictated to as to what I shall do or think in this disease. I am in favor of a correct diagnosis, which I think but very few men can make differentially, and also in favor of a definite pathology of its progressive stages, as already well defined by writers, and whatever else may or can be known of the disease before we have determined to at once cut into and dissect out or remove what has always belonged to him, unless we assume that man was originated from a gorilla in the upward scale, and did not have an appendix at first.

"Extreme Positions." Dr. Morris says "it makes a difference whether an extreme position is based upon knowledge or theory. The subject of appendicitis is so thoroughly understood by a *part* of the profession, and data so well classified, that we can now maintain the *extreme* position that operation should be done as soon as diagnosis is made."

Readers here will please notice that only a *part* of the profession (which part we are left to infer) is the New York portion of it, and the rest know nothing about it. Again, he admits his position is an *extreme* one and a *radical* one, and in view of all that is known to us in the West, where we see it perhaps as often as elsewhere, we are modest enough to say that the Doctor has mistaken his audience, if he supposes that men believe that all the facts of this disease lie in the immediate environment of the writer, who has assumed to say what must be done in any given case. I presume it will be admitted that on the first attack of pain, it can not be said: This is a case and operation must be made or the patient will die. This is a bold barefaced assumption, because my own considerable experience contradicts it. He cites diphtheria, etc., as infection, and reaches the other conclusion that the appendix is infected and must be removed to prevent further infection. We will take peritonitis. It may be simple or infecting. Does Dr. Morris, or any other man, open the abdomen, on diagnosis, to remove the infecting cause. Nay, he can not, he does not know what is the cause, and yet these cases where my own judgment would say to open the abdomen and disinfect it, as giving the best chances for life, are not so fully accepted by the cautious, honest surgeon, who values a human life more than he does his reputation or applause of men. Dr. Morris writes and talks like a man who did not intend to admit that there was but one side, that all other men were color-blind and he alone could see the *white* light. He talks as if the question had been already adjudicated and settled and he was the judge upon the bench to deliver the opinion, whereas he ought to remember that the profession of the United States and the world is but the great intelligent jury, who are determining the facts and evidence, and the time has not come for the judge to deliver his opinion to the jury. He says himself he is making an effort to gather up the statistics (that is, facts), and if so the evidence is not all in, nor the case closed. I quote a few lines from another (western man) of the medical profession, who says: "It is our opinion that operative surgery has been carried to an alarming extent; formidable operations involving the *lives of patients* have been performed upon the most trivial pretext or excuse. It is of daily occurrence to hear of women being submitted to operations, dangerous in themselves, for ailments that have been successfully relieved in the past by medication, and perhaps not one in ten, who may happen to survive the operation, are cured, and often are miserable sufferers the balance of life, while those who have succumbed and gone out of life are legion." He says further (American surgeons hear this arraignment of your surgery): "I do not hesitate to say, without fear of *successful contradiction*, that if the statistics were carefully procured the number of deaths from the effects of modern surgery, in the past ten years, will outnumber the deaths in both American armies during the late rebellion." I do not suppose it is so large (it may be) if we but reflect that in every city and town, and possibly at every cross roads, there is one or more surgeons who supposes "he carries his star in his brain," and is prepared, as he thinks, to diagnose and operate on any case presented to him, and, like Dr. Morris, is making cases for *statistics* and record.

"Conservatism," "philologists," "radicals."—If we look over this ground the Doctor has seen fit to broach, we find only the same original idea of the man who imagines he is the old schoolmaster, or pedagogue, and imbued with the idea of hammering into his pupils his one idea: "I am the master of this small confederacy and you are subjects," viz., pupils. It is but a trite saying that such an idea is but a simple monarchy, which form of government becomes dissipated into thin air when pupils grow up, as it is now in Cuba, while Spain refuses to be convinced. What does he want to invoke the aid of philologists for in this question; because somebody used a word in Webster's Unabridged which is well understood,

where men are vered in the use of words to express ideas, and there is no necessity to call the attention of philologists to the use made of it. There is a degree of reckless surgery in many directions which is noticeable and we call a halt on this line, to say that the principles of pathology have been guiding us in determining our conditions along these lines, and "that every case should be operated upon as soon as diagnosis is made" is, to my mind, to ignore vital force and all other conditions having relation thereto; is a principle of surgical practice I have never subscribed to, and I am guided by the best pathologists of the past ages as to what inflammation is in its essential character, as well as its results upon the tissues involved. I know these things as well, I presume, as Dr. Morris; but I claim the right to do my own thinking in my own way, guided as I always am by the signals of our science and art, as well as by the principles of a conservative regard for human life and suffering. I know he claims the results of statistics to prove that under "proper surgical treatment" at the proper time, has been shown to be less than 1 per cent. in the hands of several American surgeons, that is, less than one death in one hundred cases. He claims this is proved. I do not accept it, because if the cases who do not recover after operation relief, are also given, we shall have a standard by which to judge of the results of operation. Figures on paper look well, but we want something more, as we have been in a number of large hospitals for six month periods and know something of the history of methods.

The unkindest cut of all by the writer under review is this, viz.: "That conservatism takes the place of knowledge." (We deny it.) That a large part of the profession is uninformed upon the subject of appendicitis, and the further suggestion that the profession is uninformed (that is, ignorant, to put it broadly) because it can not have learned "the unwieldy sum total of our advanced medical knowledge." Now, it is clear to every well balanced mind, on reading Dr. Morris's article, that he is in a state of mind. Just what that is would require possibly a *lunatico-inquirendo* into the mental question, before giving any value to such statements regarding the general medical profession of this country.

"Members of the profession to use their own judgment about the propriety of operation." If not, who shall decide? When doctors differ who shall decide? Now again: "Shall we let members of the profession all use their own judgment, or shall we ask the men who are thoroughly familiar with the subject to teach principles and make rules for aiding those whose opportunities for gaining accurate information have been more limited." Look at the presumption and the assumption of such a proposition to the American profession. When in every important city and town, and those also less so, there are hospitals and sanitariums as thoroughly equipped with men and modern means as even those of New York City, and men of much better balanced minds than the author of the paper under review, who are just as capable of investigation with the microscope and tests, and the knife, as our writer, hence it is downright presumption and ignorance of the facts of the qualification of the American surgeon, to have written such a diatribe against them. The writer from New York had better get out and come West and mingle with the profession more fully and freely in their State and county, and perhaps also the National conventions, and then go with them to the hospital fields of labor, and also to the private bedside of a large and very intelligent and educated clientele, and he will begin to conclude he does not know it all and that possibly among all of these he may gather up some new facts about *bacteria* and results upon tissues, or the methods of performing successful operations upon his patients. It certainly is not probable or possible that all the knowledge of this subject, which has called out so much discussion and airing of surgical opinion, is found with Dr. Morris, and he at least ought to have learned so much as this, that an attempt to belittle the knowledge of his confreres in the general profession is a calumny which deserves to be widely resented, and the other spirit of generous confidence and yet independent and cautious statement in all medical investigation should be recognized as the inalienable right of him who devotes himself to the good of others and advancement of the profession to which "I (Dr. Morris) have sworn allegiance."

I, not more than others, my dear sir, who have spent a lifetime in learning "what is truth," am still, with others, asking the same question. But Dr. Morris has not answered it upon this question, as is already well understood. We are open to the truth and say nothing about the *ipse dixit*, but we know and see the truth, when not offensively paraded before us, that in me lies the truth, all the truth of this question. Other men have some experience along this line, and as all truth is a unit it might be just as well if it was not projected so forcibly that, like a cannon ball, it overcomes all our sense of appreciation. This is but suggestive, however, to the Doctor, as it seems to me and I think will readily appear to others, that he himself is "intoxicated" with the "spirit of controversy," which he charges upon another. And in winding up his article he says: "Call it intolerance if you will, but I have no motive excepting that of being useful to the profession to which I have sworn allegiance." So be it, yet I trust in future he will stand behind the utterances (if for truth) and the "truth shall make men free," if they shall perceive it, more than the man. We shall rest just here and say, come on with your facts, your statistics, your experiences, if you have any, and let us compare notes and let there be an end of all this which from the first was sought to be avoided, but was drawn out finally by references and statements, which indicated that the writer was either "intoxicated" with his "spirit of controversy," or he had set himself the ignoble task of illuminating the benighted and ignorant profession, as it had not yet learned the density of the ignorance which had covered the professional mind upon this most important question, which has come down to the few years of this closing nineteenth century, to receive the flash-light of transparent truth in the *ipse dixit*. We will receive the truth, though it blind us.

R. E. HAUGHTON, M.D.

(Finis.)

NEW INSTRUMENTS.

EUREKA HOT-WATER VAGINAL APPLICATOR.

BY S. L. WEST, M.D.,
PHILADELPHIA, PA.

My apology for presenting a new hot-water vaginal applicator to the medical profession is that so far no approved method of applying hot water internally to the female pelvic organs is at our command; and the great necessity for prompt relief of the many minor ills arising from perverted and suppressed functions of those organs demands some commendable appliance. The hot water douche is only an apology for a better method of accomplishing the great demand for local treatment of those organs. To say the least, it is attended with discomfort and fatigue to the patient, and, as used by the majority of patients, its benefits are questionable.

Figure 1.

The merits of the "Eureka Hot-Water Vaginal Applicator," which is here illustrated, at once commend it to the attention and approval of the medical profession. Its application may be briefly stated as follows: Freely soap the rubber bag (never use vaselins nor oils) and return or replace it within its holder, and open the cut-off on discharge of the rubber tube; place a pitcher of hot water, the hotter the better, conveniently near the side of the couch or bed, and drop the ends of the rubber tubes of the applicator into the pitcher; the patient reclines upon a couch or bed, on her back, with legs drawn up and knees abducted, and taking the applicator in either hand to suit her convenience, introduces the vaginal end of the applicator into the vaginal orifice, passing it up until the flange of

the applicator comes in contact with the labia, then placing the index and middle fingers of the other hand in the rings on the piston, she presses the rubber bag as high up into the vagina as can be comfortably borne, as shown by cut No. 2, holding the applicator in this position, and taking the rubber bulb on the feed tube in the other hand, she grips it two or three times, allowing the water to pass up through the rubber bag and flow out through the discharge tube. This removes the air from the rubber bag. Now close the cut-off and continue to pump water into the rubber bag. The amount of water required to be pumped into the rubber bag is determined by the discomfort produced by distension of the pelvic viscera, as shown in cut No. 3. As the parts become tolerant of the pressure, pump in more water. If it be desirable to continue the operation for fifteen minutes or half an hour, especially in chronic pelvic cellulitis attended with exudates, it will be well to empty and refill the vaginal bag, without removal, several times during the operation, thus producing the highest order of massage.

Figure 2.

Figure 3.

After a varied experience in the use of the "Eureka Hot-Water Vaginal Applicator," covering a period of several months, I respectfully beg to refer especially to the following: In dysmenorrhea it gives prompt and immediate relief, relaxing the tissues and thereby promoting the menstrual flow. In climatic and neuralgic pains of the pelvic organs and viscera, it has no equal in promptly relieving the pain. In pelvic distress, heavy weight and bearing-down pains, the results of long standing or fatiguing walks, it acts like magic, restores the parts to a normal position and rapidly promotes absorption of the local congestion. In chronic pelvic cellulitis with inflammatory exudates and adhesions, it, under the relaxing influence of the hot water and expansion or equal tension of the tissues, most effectually breaks up the adhesions and rapidly promotes the absorption of the exudates.

BOOK NOTICES.

Scientific Memoirs by Medical Officers of the Army of India. Edited by Surgeon-Major-General J. CLEGGHORN, M.D., C. S. I., Director-General of the Indian Medical Service and published from the office of the Superintendent of Government Printing, Calcutta.

This work has just reached this country. It is a small quarto of 130 pages beautifully illustrated with chromolithographed plates. It contains five papers, the first "On Choleraic and Other Commas," by Surgeon-Lieutenant-Colonel D. D. Cunningham, in which he gives interesting articles under sub-headings as: A description of some new species of commas occurring in association with cholera in Calcutta; comma-bacilli occurring in bodies of water apart from the existence of any cholera in the vicinity, etc. Under the heading, "On the relation of vibronic organisms to cholera" he states that the continued study of the bacteriology of cholera in Calcutta has in no way caused him to modify the views which he has on several previous occasions expressed in regard to the absurdity of talking of "the cholera bacillus." The longer the question is investigated in the endemic area of the disease, as represented by Calcutta, more and more evidence accumulates to show that the choleraic condition is not necessarily associated with the presence or predominance of any one species of vibrio within the intestinal tract, and that any assumption that such an association necessarily exists is merely founded on the fact that Professor Koch when in Calcutta, was either profoundly ignorant of vibronic schizomycetes as a group, or that owing to his brief and limited local experience in the locality, he accidentally encountered only a single species in connection with the few cases of cholera which he had the opportunity of investigating. At the same time it must be allowed that he was the first observer who drew attention to the undoubted fact that a very special relation does exist between the occurrence of the disease and the predominance of the vibronic schizomycetes within the digestive tract, for although a certain number of exceptional cases do occur in which the choleraic condition exists apart from the presence of any abnormal predominance of intestinal vibrios, there can be no question whatever that an association of the disease with such predominance is normal. The author concludes by insisting on certain facts: 1. Artificial administration of comma-bacilla very rarely serves to induce cholera. 2. Commas may be present in the intestinal contents of those to whom they have been administered without any evidence of the establishment of the choleraic condition. 3. Cholera may be present apart from any evidence of commas in the intestinal tract, and the numbers of vibrios and severity of the case do not necessarily run parallel. 4. The administration of different species of commas may be followed by the development of the choleraic state. 5. The physiologic properties of commas and other schizomycetes may unequivocally vary very greatly under different circumstances, and consequently the nature of the products to which they give rise in the substratum must also vary greatly. The second paper consists of notes on the malarial parasite as observed in the blood during life, and in the tissues postmortem at Lahore, Punjab, by Surgeon-Captain J. Murray. He presents fine plates showing stages in the development of the quartan parasite, the tertian parasite, the quotidian parasite and those of malignant remittents. He cites many European observers but does not appear to be aware that any work of this kind has been done at the Johns Hopkins University. Then follows a paper in which Surgeon-Captain Leonard Rogers presents some observations and statistics to show that the incidence of malarial fevers is proportioned to the height and fluctuations of the ground water-level. The last two are by Dr. Cunningham: one on the results of experiments on the action of various reputed antidotes to snake venom, conducted during

the season 1895-96; the other on certain fungal and algal diseases affecting economic plants in India. The most important of the conclusions reached by Dr. Cunningham's experiments were: 1. The serum of the blood of animals which have been artificially immunized to the action of lethal doses of snake venoms by means of habitual and cumulative treatment with the latter, unequivocally possesses antidotal properties, and hence may fairly be denominated antivenene. 2. The term antivenene is, however, of generic, not specific value, for the antidotal material contained in the blood of animals which have been artificially immunized against colubrine venom is inert against viperine venom and *vice versa*.

Diseases of the Eye. By EDWARD NETTLESHIP, F.R.C.S., Ophthalmic Surgeon at St. Thomas' Hospital, London; Surgeon to the royal London (Morefields) Ophthalmic Hospital. Revised and edited by W. T. HOLMES SPICER, M.D., M.A., F.R.C.S., Ophthalmic Surgeon to the Metropolitan Hospital and to the Victoria Hospital for Children. Fifth American from the Sixth English Edition. With a supplement on color-blindness by WILLIAM THOMPSON, M.D., Emeritus Professor of Ophthalmology in the Jefferson Medical College of Philadelphia. With two colored plates and 161 engravings. Philadelphia and New York: Lea Brothers & Co. 1897.

A book which has passed through five editions needs no special recommendation. It is sufficient to say the present edition is fully up to date. It is unquestionably the best compendium on diseases of the eye ever written in the English language and, therefore, justly recommended in many medical colleges, for recitation work.

The supplement by Dr. William Thomson, on the practical examination of railroad employees for color-blindness, gives the work an additional value to physicians engaged in railroad service, as there is no one who can speak more authoritatively on this subject or who has more practical experience in this work than the venerable emeritus professor of ophthalmology in the Jefferson Medical College.

Annual and Analytical Cyclopaedia of Practical Medicine. By CHARLES E. DE M. SAJOUS, M.D., and 100 Associated Editors, assisted by Corresponding Editors, collaborators and correspondents. Illustrated with chromo-lithographs, engraving and maps. Vol. i. Philadelphia, New York and Chicago: The F. A. Davis Company, publishers. 1898. Price, cloth \$5.00.

After ten years publication of the *Annual of the Universal Medical Sciences* in a series of five volumes every year, the plan has been changed so that hereafter one volume appears every six months and the whole alphabet will be covered in three years. Every three years therefore the subscribers will have a six-volume reference system which will cover the most that is valuable in the medical literature of the period. The volume before us is very handsome, attractively presented and is arranged alphabetically. The illustrations are fine; the paper and type are excellent.

We think in its present arrangement the "Annual" will be found more useful than heretofore because of its alphabetic arrangement.

A System of Medicine by Many Writers. Edited by THOMAS CLIFFORD ALLBUTT. Vol. vi. Pp. 1058. New York: The Macmillan Company, 1898. [From A. C. McClurg & Company, Chicago.] Price \$5.00.

This volume is devoted to diseases of the respiratory organs in which are articles by Dr. Wm. Ewart, Dr. P. H. Pye-Smith, Dr. Percy Kidd, Dr. J. T. Arlidge, Dr. Rolleston, Dr. Kingston Fowler and Dr. James F. Goodhart; Diseases of the pleura by Dr. Samuel West, Dr. Gee, Dr. Herringham and Dr. D. W. Finley; diseases of the circulatory system by Professor Michael Foster, Dr. Monckton Copeman, Prof. Sherrington, Prof. Allbutt, Dr. Sidney Coupland, Dr. Samuel West, Dr. Wickham Legg, Dr. John Thomson, Dr. Stephen Mackenzie, Mr. W. Johnson Smith, Dr. Chasle, Dr. Robert Muir, Dr. Dickinson, Dr. Laurence Humphry, Dr. F. T. Roberts, Dr. Thomas Oliver, Prof. Dreschfeld, Sir R. Douglass Powell and Dr. Ernest Sarsen.

There is a story in the author's preface which has a direct interest for American readers. He says: "An article by Prof. Welch on 'thrombosis and embolism' was to have been in my hands in ample time for the publication of this volume last Christmas. . . . Unhappily before the completion of his task Prof. Welch found himself committed to a desperate fight for the freedom of physiological research in the United States. As President of the Congress of American Physicians and Surgeons the duty fell upon him of organizing the profession in opposition to a bill now before Congress charged with restrictions so vexatious that all enlightened medical and scientific men in America consider that its enactment would be nothing less than a calamity. In addition to his laboratory and lecturing work Dr. Welch had to write innumerable letters, prepare papers and documents, organize committees, visit Washington repeatedly, have interviews with senators. He is unkind enough to add that all this trouble came from England where if your scientific men had made any sort of courageous stand twenty years ago I should not have been sacrificing my time and energies in this way. I am disposed to think that the trouble that I have caused you is a judgment for the delinquencies of your countrymen in this matter. Such are the uncertainties in the course of political business, that although Prof. Welch expected every week that the matter would come to a vote and thus liberate him to fulfill his obligations to me, yet week after week he has been disappointed and compelled to keep up agitation and organization. Even yet the fate of the bill is not sealed. Had Prof. Welch foreseen this grievous delay he would have withdrawn from his engagement in time for me to place the article in the hands of another contributor. This story I have ventured to tell at some length because it contains an interest and perhaps a warning for us all."

It will perhaps interest Prof. Allbutt to know that at adjournment of Congress the Anti-Vivisection bill remained unadjusted, but it is not believed that it can now pass either house of Congress. Nevertheless the profession in this country will take advantage of the summer vacation and personal contact with members of Congress and the Senators; to inform them of the consequences of this most ill-advised measure.

The work under consideration represents the present state of British medicine as set forth by some of its ablest exponents.

Hay Fever and its Successful Treatment. By W. C. HOLLOPETER, A.M., M.D. Pp. 137. Philadelphia: P. Blakiston Sons & Company, 1898. Price, \$1.00.

The author says: "Having had remarkable and uniform success with the simple treatment of hay fever for the last ten years, during which time I have given complete relief to over 200 patients in my private practice, and having made a thorough clinical study of this affection, as well as an exhaustive review of the literature relating to it, I feel justified in presenting the results of my labors in this short treatise."

The treatment advocated by the author is strict sterilization of nasopharynx—daily sterilization. Surgical treatment is indicated, according to the author, only when gross lesions exist. In old cases the treatment should commence two or three weeks before the anticipated recurrence of the paroxysms.

The author has conferred a benefit on the profession in making his views public, for whether others sustain in actual practice the therapeutics here recommended or not, careful cleansing of the nasal passage must result in good, and many patients be relieved from the cruel and heroic measures so frequently recommended.

A copious bibliography concludes the book.

Schenk's Theory. The Determination of Sex. By Dr. LEOPOLD SCHENK. Authorized Translation. Pp. 222. The Werner Company: Chicago, Akron, Ohio, and New York, 1898.

The lay press has extolled this book to an extent that renders it unnecessary for a medical journal to say much. The

amount of sugar in the system, according to the author, determines the sex of progeny. For example, a woman with diabetes is nearly certain to have female children. And in all cases in which there is a predominance of female offspring the Trommer test shows the presence of sugar. The natural sweetness of the female sex is thus biologically accounted for. The question of diet is therefore the controlling factor under the Schenk theory. When male offspring are desired the diet should be on antidiabetic lines.

PUBLIC HEALTH.

Health in Chicago.—The report of the Department of Health for June gives 1581 deaths for the month, a rate of 0.98 per 1000 as compared with 1 per 1000 for June 1897 and 1.17 for June 1896. Of these deaths, 296 were of persons under one year old and 181 between 1 and 5 years. The principal causes were: Diseases of the nervous system, 224; consumption, 218; pneumonia, 142; diseases of the heart, 101; acute intestinal diseases, 88; cancer, 73; bronchitis, 47; typhoid fever, 35; diphtheria and membranous croup, 30.

Death-rate in Diphtheria.—Professor Kassowitz of Vienna denounces antitoxin, stating that the published percentages are misleading and that the actual mortality from diphtheria has not diminished in recent years as claimed. He cited statistics from Moscow, London, New York, etc., which prove that the number of deaths has not decreased, whatever the percentages may show, while statistics everywhere prove that tracheotomy, primary or secondary (after intubation), is still followed by death in 70 to 90 per cent., that the number of cases of consecutive paralysis (heart death) has actually increased, and that renal complications are not affected by the antitoxin, while croup continues its course unchecked by the injections. He even refuses to consider the Klebs-Loeffler bacillus the specific cause of diphtheria, which he says is yet to be discovered. In the cities (Vienna, Paris) in which the mortality is actually lower of recent years, the disease has been of a milder type.

NECROLOGY.

EDWARD HAMILTON KIDDER, M.D., Fall River, Mass., died July 16, 1898, after an illness of some two or three months. Dr. Kidder was 32 years of age and a native of Lincoln, Mass. He attended Harvard University, graduating in the class of '88. After a year of teaching he went abroad for study and observation in hospital work. On his return he studied medicine, graduating from the Harvard Medical School in the class of '93. He was given an appointment as house surgeon at the Massachusetts General Hospital, serving nineteen months. He was especially devoted to the study and practice of surgery and was notably successful in his hospital practice in this work. He came to Fall River in 1894 and was a leading spirit in the organization of the Emergency Hospital and the Training School connected with it, and the success of these institutions has been largely due to his enthusiastic and energetic support. In the death of Dr. Kidder the profession and the city of Fall River alike suffer a distinct and appreciable loss. He was a man of unusually fine spirit, unassuming of himself in the work he had to do. His early end was in part the result of overwork. Dr. Kidder was a member of the Massachusetts Medical Society, the Fall River Medical Society and the Harvard Medical Alumni Association.

ALAN PENNEMAN SMITH, M.D., died July 18, at his home in Baltimore, M.D., in which city he was born in 1840. He was a son of Dr. Nathan Ryno Smith, a graduate of Princeton, and in 1861 of the University of Maryland, Medical Department. As one of the trustees of the Johns Hopkins Uni-

versity and as a member of many societies he was widely known despite his modest and unobtrusive ways. Early in his career he was in high repute as a lithotomist. Six children survive him, one of whom is a physician. He had many friends in the profession and out of it.

JOHN HEWITT WILSON, M.D., Glasgow, Scotland, 1844, of New York city, was found dead in his room July 15. Cardiac disease is given as the cause of death. He was born in Auchnacloy county, Tyrone, Ireland, in 1818, and came to America in the year after his graduation. Two daughters are his survivors.

R. O. MOFFAT, M.D., a young physician of Toronto, Canada, died in a dentist's chair from the effects of chloroform, July 18.

JAMES T. BALL, M.D., Colorado City, Colo., died near Judson, Ind., July 15, aged 39 years.—**F. H. Bodenius, M.D.,** University of Heidelberg, Germany, 1869, of Madison, Wis., died at Baltimore, Md., July 21, aged 53 years.—**Jacob Boon, M.D.,** Glen Olden, Pa., July 17, aged 61 years.—**Frederick W. Vogel, M.D.,** Boston, University of Halle, Germany, 1868, died July 16, aged 52 years.—**Henry E. Werner, M.D.,** Rush Medical 1888, died at his home, Le Claire, Iowa, July 16.

DEATHS ABROAD.—**F. Cohn,** professor of botany at Breslau, whose name will be remembered with those of Nägeli, Pasteur and Koch, as one of the founders of bacteriology.—**Dr. Levieux,** formerly physician to the Bordeaux Hospitals, corresponding member of the Académie de Médecine, aged 80 years.—**Dr. Anton R. Kerner von Marilaun,** professor of botany in the University of Vienna, aged 66 years.

SOCIETY NEWS.

Medical Temperance Association.—This Association, organized at the Washington meeting of the AMERICAN MEDICAL ASSOCIATION in 1891, has attracted a good deal of attention lately. Its particular object is the special medical study of alcohol as a medicine and beverage. Its members are almost all members of the AMERICAN MEDICAL ASSOCIATION, and the annual meeting is held at the same place and time as that of the ASSOCIATION. For several years it has held a summer meeting at Staten Island, in July, which has been largely attended by philanthropists and temperance reformers as well as medical men. The particular object of these meetings has been to group and collate a mass of testimony which has been both exaggerated and minimized by physicians and temperance advocates, and to point out the real facts and the lines of investigation now being pursued. These meetings have followed National gatherings of reformers and been very influential in many ways. The meeting this year, July 5 and 6, followed a temperance congress of four days' length, closing the day before the medical convention began. The papers presented were purely scientific, but were listened to with much interest by a large mixed audience. Both the papers and discussions were temperate in tone and very reasonable suggestive presentations of facts and conclusions. Meetings of this character exercise a strong influence and are of great value to both the profession and the laity, correcting popular errors and rousing up new interest in a subject of increasing importance in every circle of society. Both the English and French societies have quarterly meetings, in which leading temperance men take part. Here the meetings are restricted to medical men. The medical side of the temperance question is a very large and almost unknown field, and increasing interest will follow the work of this society in the future.

The French Congress of Surgery will meet at Paris, October 17 to 22, with Professor Le Dentu in the chair. Nephrotomy will be the subject of addresses by Guyon and Albarran, and the "Treatment of Goiter" (exclusive of cancerous and exophthalmic goiter), by Reverdin of Geneva. For further particulars address Lucien Piqué, Secretary, rue de l'Ély 8, Paris.

Mississippi Valley Medical Association.—The twenty-fourth annual meeting of this association will be held at Nashville, Tenn., October 11-14, under the presidency of Dr. John Young Brown of St. Louis, Mo. The annual addresses will be made by Dr. Jas. T. Whittaker of Cincinnati, on medicine, and by Dr. Geo. Ben Johnson of Richmond, Va., on surgery. Titles of papers should be sent to the secretary, Dr. Henry E. Tuley, 111 West Kentucky Street, Louisville, Ky., as early as possible. Reduced rates on all railroads will be granted on the certificate plan.

Cumberland County Medical Society.—A meeting of the Cumberland County Medical Society was held at Hotel Cumberland, Bridgeton, N. J., July 12, and was presided over by Vice-President Dr. J. B. Ware. Dr. T. G. Davis of Bridgeton read a paper on "Nephritis in Children." Dr. H. W. Elmer, as delegate, reported on the AMERICAN MEDICAL ASSOCIATION, and Dr. L. L. Hand of Leesburgh on the State Medical Society.

The French Congress of Gynecology, Obstetrics and Pediatrics will meet at Marseilles, October 8-15. The subjects to be discussed are: Extra-uterine pregnancies; auto-intoxications during pregnancy; congenital herniae; microbial associations in diphtheria; school children's dyspepsia; infantile cardiopathy; the purpura, diplegia and colitis of infancy and paralytic club-foot.

MISCELLANY.

Not a Good Showing.—An English inspection reports that out of 8125 children scarcely 40 per cent. have normal vision in both eyes.

Chicago Polyclinic.—This flourishing school has paid off the last of its indebtedness, and the building and grounds now belong to its Faculty without incumbrance.

Dr. Eugene S. Talbot, on account of his original investigations, has been elected honorary member of the Odontological Society of Spain.

Formaldehyde Only a Surface Sterilizer.—Dr. Harrington of the Harvard Medical School, after experiments, concludes that this gas has no penetrating power in the presence of moisture.

The Penalty of Philanthropy Remitted.—The Russian branch of the Red Cross Society has handsomely recognized by a pension of one thousand rubles, the services of M. Henri Durant of Geneva, now in poverty. This sum is to be paid annually.

Origin of Red Blood Corpuscles.—Dr. A. Pappenheim (*Virchow's Archives*, Band 151), after attaining his best results by fixing with heat at 120 degrees C. for five or ten minutes, then dipping five seconds in a concentrated sublimate solution and staining with alum carmin—methyl green, concludes that the red blood corpuscles are derived from the basophile leucocytes.

Sleep for Children.—(*Pediatrics*, Vol. v, No. 2; *Am. Medico-Surgical Bulletin*, July 10, 1898). The approximate period of sleep for children is given as between one and two years, six to eight waking hours; between four and six years, nine to eleven waking hours; between nine and 13 years fourteen to sixteen waking hours. Still the comment is that perhaps too much stress is laid upon the harm of over-sleeping, particularly in young children.

Hysteric vs. True Peritonitis.—Hopkins, *Colonial Medical Journal*; *Am. Medico-Surgical Bulletin*, maintains the rarity of the simulation of acute diffused peritonitis on the part of the hysteric. In neuropathic women the localized inflammatory affections are at times closely counterfeited. In hysteric peritonitis a slight touch of the skin is more distressing than deep pressure, although in neuropathic patients deep pressure in the hypochondriac region causes intense suffering. Pulse and

temperature in simulated peritonitis are usually about normal, while vomiting is often present, but never nausea. Besides, the vomiting does not become fecal.

Correction of Curved Tibia.—Hopkins in the *Annals of Surgery* for July, describes an operation which consists of a combination, in a modified form, of osteotomy and osteoclasis. In reality, he performs two operations, incomplete osteotomy and osteoclasis; in the first, dividing the bone, with a chisel, one-half of its thickness at its inner curve. When the skin wound is healed, but before bone repair has restored the original strength, the osteoclast is applied and the deformity corrected by a fracture at the weak point of the bone. He reports one case.

In Favor of the Post-Graduate Hospital.—The report of a special committee appointed to investigate charges against the New York Post Graduate Medical School and Hospital was adopted at a meeting of the State Board of Charities today. The charges were that money given for the endowment of beds had been misapplied, and that the city of New York had paid for children who had never been in the institution. The report says that the charges were not sustained.—*N. Y. Sun*, July 13.

Cerebro-spinal Fever.—Osler (*Maryland Medical Journal*, July 16) reports seven cases. He says the disease is never pandemic, but the outbreak is more or less localized and there is an absence of any continuous extension. He considers the treatment still in an unsatisfactory state, and in four of his cases recovery did not seem to follow the use of any special drug nor any special treatment. He advises sponging, etc., for fever, also an ice-cap and opium for the pain. Counter-irritation he considers important, the best method being to "touch along the spinal column lightly with the Paquelin cautery."

Multiple Neuritis.—Ruffin (*Medical Record*, July 9), points out that the diseases with which multiple neuritis are confounded are acute ascending paralysis of Landry, diffuse myelitis and spinal meningitis, anterior poliomyelitis and locomotor ataxia, it being most apt to be confounded with the latter. He believes that absolute rest in bed should be insisted on in all forms of the disease, and symptomatic treatment be resorted to. He advises massage as of great importance, often using it from the beginning of the attack. Aside from alcohol, he considers lead poisoning the most frequent cause for peripheral neuritis, paralysis of the wrist extensors being the most striking feature.

Cholelithiasis in Infancy and Childhood.—Wendel (*Medical Record* for July 9) writes concerning the symptomatology and diagnosis of these cases, basing his paper on observations of sixteen cases in persons under eight years of age. He confirms former observations that in young persons jaundice caused by gall stones without pain is rare, and says that in young individuals, as a rule, the expulsive faculty of the bile duct does not permit the calculi to remain long in the common duct, and in these cases jaundice is so slight as to be apt to be overlooked. He believes that in every case of convulsion occurring without premonition, gall stone colic should not be excluded as a cause until a careful examination has been made, this being often overlooked in the case of young persons.

Milk for Infant Feeding.—Freeman presents a summary of the answers received to questions sent to the members of the American Pediatric Society as to whether the milk used for infant feeding should be heated for the purpose of killing germs, and if so, at what temperature and how long continued, in the *Archives of Pediatrics* for July. The replies showed a remarkable unanimity of opinion, the predominating opinion being that raw milk would be the best food if it were possible to obtain it clean, while a considerable number evidenced their willingness to take their chances with raw milk during certain seasons and under certain conditions. He believes that under

present dairy hygiene some sort of sterilization must be used, and favors pasteurization at a temperature of about 155 degrees F. for thirty minutes, followed by rapid cooling, as such temperature destroys the germs of diphtheria, typhoid fever and tuberculosis. This at the same time does not give the milk a "cooked milk" taste, and chemical changes would not occur until a temperature of 10 degrees higher was obtained.

Suture Material.—Gordon (*Medical News*, July 16), in a paper on "Suture and Ligature Material—Absorbable and Non-Absorbable," believes that silver wire is entitled to preference over nearly all kinds of non-absorbable material, silkworm gut coming nearer to this than any other. His conclusions are: 1. All suture material unabsorbed must necessarily have more or less exudate about it. 2. Such exudate is of lower vitality than normal repair where tissues are just approximated and not strangulated. 3. A few days only are necessary to insure repair, if there is no infection, and therefore in cases where no great amount of strain exists, absorbable sutures only are needed. 4. Where continual strain on the parts is inevitable, non-absorbable sutures should be used for at least two weeks, but should be so placed as to be removable. 5. For such sutures silkworm gut seems to be the best, as it can be made sterile and kept so. 6. For all other purposes catgut is sufficient. 7. Inflammation is always destructive to complete repair. 8. Inflammation is always due to infection. 9. Sterile catgut or kangaroo tendon should therefore fulfil all indications for suture or ligature material, with the exceptions named.

Anomalous Cords of the Heart.—Lewis (*Philadelphia Medical Journal* of July 16) in a dissection of eighty hearts, found fifty-one showing anomalous cords. Some of the hearts were from monsters, a few were abnormal only as to their tendinous cords and the others pathologic. Thirty-two of the fifty-one had abnormal bands across the cavity of the left ventricle and in twelve of these more than one such band, some being branched or forming a net-work across the cavity. As to the right ventricle, twelve contained one or more such bands, and in five of these they were multiple. Six of the above showed aberrant cordæ tendineæ in both ventricles, and in six there were one or more cords, or a network running vertically across the posterior appendix of the right auricle. Thin cords singly or in net-work occurred in eight cases in addition to or in place of the valve of the coronary vein, and four hearts had bands stretched between the papillary muscles. No case showed a cord across the cavity of the left auricle. He believes that the aberrant cords are of clinical significance in adding murmurs which obscure the cardiac sounds, or serving as points on which the blood may clot, or interfering with the complete opening or closing of the mitral or tricuspid valves.

That Tuberculosis Number.—We notice that our esteemed contemporary, the *Philadelphia Medical Journal*, is patting the *London Practitioner* on the back for publishing a recent issue entirely devoted to tuberculosis, a movement which originated with the *JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* with the issue of Feb. 5, 1898, but which our valued contemporary did not venture to make mention of, although in that issue of the *JOURNAL* there appeared thirteen original articles, comprising forty pages of two columns each, on various phases of tuberculosis, also two exhaustive editorials and several pages of miscellaneous items on the subject. In addition to this mass of matter on this special subject, the *JOURNAL* of that issue also contained other editorial and department matter on general subjects. These papers were from the pens of leading men in medicine throughout the country, and a column of the *JOURNAL* is practically equivalent, in amount, to a page of the *Practitioner*. When it is remembered that the *Practitioner* is a monthly publication and that this issue of the *JOURNAL* was our regular weekly edition, the matter is still more noteworthy.

In Praise of Ebrity.—To show how the times have changed, let it be known that an old and curious book exists upon the virtues of alcoholic addiction. It was printed for E. Curl, against Catherine Street, in the Strand, London, in 1723, and is marked "Price Five Shillings." The title is as follows: "Ebrietatis Encomium, or the Praise of Drunkenness; wherein is authentically and most evidently proved, the necessity of frequently getting drunk; and that the practice of getting drunk is most ancient, primitive, and catholic. Confirmed by the example of Heathens, Turks, Infidels, Primitive Christians, Saints, Popes, Bishops, Doctors, Philosophers, Poets, Freemasons, and other men of learning in all ages. By Boniface Oinophilus, de Monte Fiascone, A. B. C."

Vinum retificans cor hominis,
Narratur et Prisci Catories,
Saepe mero caluisse virtus.

—Horatius.

The author lays down the following rules for getting drunk, to-wit: 1. Not too often. 2. In good company. 3. With good wine. 4. At convenient times. 5. Force no one to drink. 6. Do not push drunkenness too far.

A Medico-Cleric gets Some Advice Gratis.—The *Lancet* tackles a would-be homeopathic clergyman as follows: "We extract the following advertisement from the Bazaar:—"

MEDICAL.—Wanted Standard Homeopathic books and drugs. Hints gratefully accepted. VICAR B.

We are happy to give "Vicar" a hint and hope he may be as grateful for it as he promises to be in the advertisement. We might multiply hints, but one hint will cover all the ground. It is that he should not interfere with what he does not understand. Suppose he drugs a person and that person dies, "Vicar" can not sign a death certificate, at least not a valid one. In that case the Coroner at the ensuing inquest would certainly make strong remarks upon "Vicar's" unfortunate position, and "Vicar" might even find himself nearer a trial for manslaughter that would be seemly in one of his cloth.

Curvature of the Neck of the Femur.—Frazier writes on this subject, sometimes called "Coxa Vara," in the *Annals of Surgery* for July. He says there is usually no relation between the physical development of the patient and the deformity. Atrophy of the muscles of the thigh is present to a greater or less extent in every case, according to the amount of functional disturbance of the joint, and in some cases the difference in circumference between the two thighs amounts to seven centimeters. The trochanter major is usually displaced upward; in many cases, upward and backward, and upward and forward in not a few cases. As to the attitude of the limb, in sixty cases in which the position was abnormal, fifty-four presented outward rotation. Occupation seems to be the predisposing cause, also sex, 70 per cent. occurring in males and 30 per cent. in females. For diagnosis, he advises examination as to the following points: atrophy; position of the trochanter in relation to Nélaton's line; relative length of extremity, measured from anterior superior spine to internal or external malleolus; actual length of extremity, measured from tip of trochanter to external or internal malleolus; extent of outward rotation; limitation of inward rotation; restriction of abduction and adduction and disturbances of flexion or extension. Treatment includes rest, extension and massage, with attention to hygiene and phosphorus internally, if there are evidences of rickets. Operative interference is reserved for cases in which the disability is pronounced.

Venomous Spiders.—Dr. Andrew Ross of New South Wales has reported a supposed case of serious toxic effect from the bite of a spider. A boy, aged 5 years, while eating some bread and butter on a doorstep, suddenly cried out and complained of being bitten on the neck behind the lobe of the right ear. He pulled his hat off and threw it on the ground, when a large black spider with a bulbous belly and red spot on the back was

discovered inside and instantly killed. Curious toxic symptoms shortly afterward began to develop in the patient. These were mainly acute pains in the legs and feet and inability to stand or walk. On examination, a large erythematous circle at the spot where the spider was supposed to have bitten him was found. The restlessness and acute suffering continued, and nothing afforded any relief. The affected part was bathed in hot water, and at short intervals strong doses of ammonia were administered and teaspoonfuls of strong brandy were given until about four wineglassfuls had been used, but the symptoms were unrelieved. It was not until five emetics had been taken and full vomiting induced that the patient began to improve. Subsequently he recovered, but his convalescence was for some days delayed by the loss of power in the lower limbs, and recurring attacks of pain. The genus to which the spider belonged was probably *lactrodictus*, of which in Australia there are two species, viz., *L. scelio* and *L. parsellii*. The bite of all species of this genus in every part where they are found, as for example in Southern Europe, California, North Carolina and New Zealand, is credited with venomous qualities in a marked degree and deaths of human beings have been reported as the result of such bites. Some dead spiders of the Australian species which were sent to Professor Kobert of the Dorpat University were found to be inert as far as poisonous properties were concerned.—*Medical Press and Circular*.

Cincinnati.

A VACCINATION STORY.—Some months ago a bona fide case of smallpox was detected in the receiving ward of the Cincinnati Hospital. He had lately been in a region known to be infected, and his latest boarding house was in a very densely inhabited part of the city, peopled for the most part by negroes. It was deemed necessary by the health department that vaccination should be carried out in this locality on a large scale. Many laughable incidents are narrated by the physicians to whom the work was assigned. The greatest difficulty was encountered in making them submit, and only threats of a "ride in the wagon" could influence the most of them. But when vaccinated, they became most zealous in pointing out to the amused officers the hiding places of others in the building. One dusky matron called up stairs after her own arm had been thoroughly vaccinated, "Mistah doctor, dar's a low-down niggah under de bed in de fron' room." One of the physicians in his enthusiasm pounced upon the bed in question, which with a crash came to the floor, scattering bed-slate and curées with equal impartiality in every direction. "Say, white men, can't ye let a feller sleep?" came from the depths of the ruins, but his earnest plea was disregarded, much to the delight of the already vaccinated darkies who had gathered around to see the fun.

San Francisco.

SAN FRANCISCO COUNTY MEDICAL SOCIETY.—At the June meeting Dr. Thorne reported a case of removal of the stomach, gastrectomy, which he stated was the fifth operation of this kind that had been made. The patient was a German woman 52 years old, and the family history was quite negative. She had done a good deal of hard work, principally at the wash-tubs, and had always had a good appetite. For about four years there had been a good deal of gastric disturbance, principally confined to pain after eating, also flatulency. When examined the tumor was found to be kidney-shaped in the left hypogastric region and freely movable. It was not differentiated from a misplaced kidney, though the two alternative conditions of cancer of the stomach and floating kidney were recognized. The patient entered the hospital on June 23, and was operated upon on June 26. All preparations had been made to remove the stomach, if the condition was found to be one of cancer of that organ upon opening the abdomen. This was found to be the case, and the operation for removal was at once undertaken. The omentum was ligated in sections and

tied off. Several adhesions were treated in the same way, and the organ at last freed from its connections. The intestine below the pylorus was seized with a strong forceps, the blades of which had been covered with rubber tubing and the stomach tied off and cut away; a similar method was employed in dealing with the cardiac end of the stomach. The esophagus had to be dissected away from adhesions and ligaments before it could be brought down low enough to tie to the intestine. The cut ends were united by means of a Murphy button reinforced by a line of sutures. During the operation the patient had been given regular doses of strychnin and whisky, hypodermically, and the total time of operation was two hours and forty-five minutes. She recovered from the anesthetic well and suffered little or no pain, but was intensely prostrated. Strychnin, whisky, digitalin, etc., were given at frequent intervals, but the patient steadily sank; she was conscious and rational until the last, but died forty hours after the operation. Her system had been so reduced by the long continuance of the disease that she was unable to rally from the slight shock of the operation. Dr. Chas. G. Levison reported several cases of operation upon the kidney, with one of nephrectomy for angioma of the left kidney, the twenty-eighth case reported as successfully operated upon. The diagnosis was very difficult, as there was no symptom except the frequent appearance of blood in the urine, which when it occurred, was in considerable amount. When there was no blood present the urine was free from casts, cells or crystals, and no indication of a diseased kidney was to be found. At the time of hemorrhage the blood and clots so filled the bladder that it was impossible to obtain any information by means of cystoscopy. It occurred to the doctor to make a trifle more pressure on the region of the kidney and see if any hemorrhage resulted; in this way he imagined he could gain some information as to which kidney was the affected one. This was tried on the left side first, and the experiment was followed in fifteen minutes by a free flow of blood. On this indication the operation was directed to the left kidney, which was found to be the site of a large angioma, located in the lower portion of the kidney. The operation was entirely successful, and the patient has quite recovered with no indication of any recurrence.

Philadelphia.

MORTALITY STATISTICS.—For the week ending June 16 there were 493 deaths, a decrease of 227 from the previous week and 135 from the same period last year. The low mortality for the week is no doubt due directly to cooler weather, there being fewer deaths noted among children.

INFECTIOUS DISEASES.—This week: Diphtheria, 14 deaths, 73 cases; scarlet fever, 27 cases; typhoid fever, 5 deaths, 50 cases. Last week: Diphtheria, 11 deaths, 49 cases; scarlet fever, 3 deaths, 17 cases; typhoid fever, 13 deaths, 50 cases.

PREVENTION OF DEATH FROM LIGHTNING.—During the 4th of July festivities, while thousands of persons were in Fairmount Park, a severe thunder-storm came on, and while there was only one or two severe flashes of lightning, one of them struck in the midst of a crowd sheltered under a tree, killing three persons instantly. It now seems that the Park Committee on further inquiry learned from several leading physicians that suspended animation following lightning stroke does not always prove fatal provided the necessary precautions are taken. Dr. J. Howard Taylor, Chief Medical Inspector of the Board of Health, is quoted as saying: "There can be no doubt that there are cases of suspended animation from lightning stroke or other electric shock just as there are such cases of drowning. There certainly ought to be rules thoroughly known by police and park guards for the treatment of victims of electric shocks. Such rules would be of especial value in saving the lives of men shocked by electric wires in case of fires, etc. The fact that death is not always instantaneous following an electric shock reflects unfavorably

on punishment of criminals by electrocution." It is also stated that the United States Weather Bureau has tabulated some imported statistics regarding this subject. "In the United States for the five years 1890-1894, 1120 lives were lost by lightning stroke or an average of 224 lives each year. Nearly all of these fatal losses occurred from the month of April to September, the maximum deaths occurring during June and July. Thickly settled communities are far less subject to lightning stroke than sparse settlements. In general the risk in the country is five times greater than in the city. Geologic conditions are also important factors, as for instance chalk is least susceptible to lightning stroke. Marl is twice as liable as chalk, clay seven times as liable, sand nine times and loam twenty-two times. Different kinds of trees are liable in different degrees. The oak is most frequently struck, while the beech is least frequently affected. Pines are struck fifteen times more frequently than the beech and the oak fifty-four times. Most generally trees struck are those standing in the clear or on the edge of forests, their height averaging from fifty-two to sixty-six feet." It is reported that the lightning strokes which recently proved fatal concur accurately with these statements. Since this subject has received the attention of the Park commissioners and physicians, it is proposed that rules be formulated for the proper guidance of park guards in resuscitating patients, such as arousing the patient, application of the cold douche, friction of the extremities, warm applications, administration of stimulants, and artificial respiration to be persisted in for at least one hour.

REPORT OF HOWARD HOSPITAL.—The 44th annual report has just been issued. The total number of new cases treated in the hospital and dispensary was 8306, compared with 8431 last year, 8438 for 1896, and 7167 for 1895. The total number of visits of patients was 32102, compared with 28180 last year and 28065 for 1896. Of the total number of new patients there were 6491 white and 1815 colored, 3911 being males and 4395 females. Nativity: United States, 6140; Ireland, 1278; Italy, 318; Russia, 221; Germany, 173; England, 129; Scotland, 47. For 1897, of 8431 cases treated, the nativity was as follows: United States, 6092; Ireland, 1447; Russia, 255; Italy, 240; Germany, 183; Scotland, 47; France, 7; Arabia, 4.

A third story has been added to the annex department and a sick diet kitchen constructed on the second floor, greatly facilitating the preparation of proper food for patients. The total receipts as shown by the treasurer's report were \$35,378.84, and the expenditures \$31,438.59, leaving a net balance in cash, March 1, 1898, of \$3,912.30.

MEDICAL EXAMINING BOARD.—As a result of the examination for licensing physicians by the State Board of Pennsylvania, 317 applicants presented themselves for examination; out of this number 271 obtained certificates, 43 failed to pass, 2 were dismissed for unfair methods, while one withdrew to join the army. A fee of \$25 must accompany each application, which fee is divided among the members of the Board. Dr. W. B. Stanton of Philadelphia received the highest general average, 91.73, out of a possible 100.

AFFECTED WITH TUBERCULOSIS.—Dr. Pearson, of the Veterinary Department of the University of Pennsylvania, and State Veterinarian, has recently made his report to Governor Hastings in regard to the work of the State Live Stock Sanitary Board. It is stated that from June 1, 1897, to June 1, 1898, 1900 cattle were inspected and the number of infected cattle was 12 per cent. The greatest number of infected cattle came from New York, New Jersey and Maryland, while some came from the Western States. Of 1000 cattle from Ohio six were found affected. Dr. Pearson has been appointed to represent Pennsylvania at the International Tuberculosis Congress at Paris, July 27 to August 3, inclusive, and is now on his way to that city.

Louisville.

LOUISVILLE MEDICAL COLLEGE.—Attorney John S. Jackman has just been appointed by the judge of the common pleas court a receiver for the Louisville Medical College property. Some weeks ago the Fidelity Trust and Safety Vault Company filed suit in the law and equity division for sale of the property, being large holders of the college paper, and a decree

of sale was ordered. An appeal was taken by Dr. Samuel Cochran to the court of appeals, and pending a decision of this, a receiver was asked to preserve the property and lease it. Several pleadings were filed in this suit, several sensational statements being made by Dr. Samuel Cochran in regard to the financial conduct of the institution.

LAWS.—Dr. Wm. V. Laws, for some time assistant to Dr. J. M. Mathews, has accepted a position in the Medico-Chirurgical College of Philadelphia, as demonstrator of surgery, where he will be associated with Prof. Wm. Rodman, formerly of this city, professor of surgery and clinical surgery. Professor Rodman will not leave for Philadelphia until September 30, having an office for the summer at Second and Walnut Streets.

MATHEWS.—Dr. J. M. Mathews, president-elect of the AMERICAN MEDICAL ASSOCIATION, and Mrs. Mathews, who have been spending some time on the California coast, have returned.

MARVIN.—Dr. J. B. Marvin and family will sail August 1 for Europe, for the summer months.

CARTLEDGE BULLITT.—The profession of Louisville have received announcements of the partnership of Dr. A. M. Cartledge and Dr. James B. Bullitt. They will office at Second and Broadway.

McMURTRY.—Dr. L. S. McMurtry will spend his vacation fishing in the Canada lakes.

MEYERS.—Dr. Sidney J. Meyers, until recently associated with Dr. Wm. L. Rodman in this city, has been appointed acting assistant surgeon in the army and has reported for duty to General Brooke at Chickmauga, Ga., in the division hospital.

ADDRESSES.—At a meeting of the Executive Committee of the Mississippi Valley Medical Association, the following were chosen to deliver the annual addresses at the next meeting in Nashville: Dr. James T. Whittaker of Cincinnati, on medicine; Dr. George Ben Johnson of Richmond, Va., on surgery.

COMMITTEES.—The following are the Committees appointed by the Chairman of the Committee of Arrangements for the next meeting of the Mississippi Medical Association: Arrangements: Duncan Eve, Chairman; W. D. Haggard, Jr., Secretary; J. A. Witherspoon, Paul F. Eve, R. E. Fort, S. S. Crockett, G. C. Savage. Reception: L. B. Graddy, Chairman; W. A. Atchison, W. D. Haggard, Sr., W. F. Glenn, W. L. Dudley, James B. Stephens, W. C. Bilbro. Entertainment: J. Y. Crawford, Chairman; W. G. Ewing, Larkin Smith, A. B. Cook, J. W. Handey. Exhibits: Dr. Dering, J. Roberts.

QUARANTINE.—The epidemic of smallpox in Jackson County has assumed such a serious aspect that, as the county court will not appropriate sufficient funds to stamp it out, the State Board of Health has, by the Executive Committee, at a meeting held at the office of Dr. Wm. Bailey, on the 21st inst., declared a rigid quarantine against Jackson county. The adjoining counties are Madison, Clay, Estell, Lee, Owsley, Laurel and Rockcastle. The Quarantine Proclamation states that "After due notice and repeated urging from this and the County Board of Health, the authorities have persistently failed to take any steps to prevent the spread of this highly dangerous and contagious disease . . . the State Board of Health of Kentucky . . . declares Jackson County and each of its inhabitants to be in quarantine, and establish the quarantine line along the entire boundary of said county, and forbids any person to enter or leave said county without a special permit from this Board, under the pains and penalties of law, which is a fine of not less than \$50, nor more than \$500, or imprisonment in the county jail of not less than sixty days, or both fine and imprisonment." This is the first time in sixteen years that an absolute quarantine has been declared in the State.

Societies.

The following recent meetings are noted:

Illinois.—Iowa and Illinois Central District Medical Association, Rock Island.

Indiana.—Mitchell District Medical Association, West Baden Springs, July 19 and 20; Tri-State Medical Association, Elkhart, July 19.

Iowa.—Botna Valley Medical Society, Atlantic, July 14.

Maryland.—Cecil County Medical Society, Elkton, July 14.

Minnesota.—Interurban Academy of Medicine, Duluth, July 20.

Missouri.—St. Louis Medical Society, July 14.

Ohio.—Eastern Ohio Medical Association, Steubenville, July 12; Muskingum County Medical Society, Zanesville, July 14; Northern Ohio District Medical Society, Fremont, July 21.

Pennsylvania.—Cumberland County Medical Society, Newville, July 12.

Texas.—Briggs Medical Society, Waxahachie, July 12; Central Texas Medical Association, Temple, July 12 and 13.

Vermont.—Rutland County Medical and Surgical Society, Burlington, July 12.

Virginia.—Seaboard Medical Association, Norfolk, July 15 and 16.

THE PUBLIC SERVICE.

Movements of Medical Officers in Active Service.

Assigned to duty with the 2d Army Corps, General Wm. M. Graham, Camp Alger, Va.: Majors Jabez N. Jackson and Wm. F. de Niedman, brigade surgeons. To the 3d Army Corps, General James F. Wade, Chickamauga Park, Ga.: Major Guy L. Edie, brigade surgeon, from San Francisco, Cal., and Acting Asst. Surgeon Robert W. Andrews from Poughkeepsie, N. Y. To the 4th Army Corps, General J. J. Coppinger, Tampa, Fla.: Major Edward Martin, brigade surgeon, relieved from duty with the 2d Corps; Capt. E. L. Munson, U. S. A., from Ft. Monroe, Va., recently from Santiago, Cuba; Capt. Allen M. Smith, U. S. A., from Ft. Hamilton, N. Y., and Capt. Champe M. McCulloch from Ft. Barrancas, Fla., and the following acting assistant surgeons: Irving E. Bennett from Ft. Delaware, Del.; Patrick H. McAndrew from Washington, D. C.; G. Moreno de la Torre from the hospital transport *Olivette*; E. A. Romig from Big Rapids, Mich., and Paul C. Hutton from Washington, D. C. To the 5th Army Corps, General Wm. R. Shafter, Santiago, Cuba: Major W. C. Gorgas, brigade surgeon, relieved from the hospital ship *Relief*; Acting Asst. Surgeons R. Fleming Jones and H. J. Thomas from Winston, N. C., to go by way of Tampa, Fla.; Acting Asst. Surgeons Aristides Agramonte and Charles T. Newkirk from Washington, D. C., to go by way of New York City; Acting Asst. Surgeons Paul Mazzuri and Myer Herman from New Orleans, La., and J. F. Archer from Shelby, Miss., to go by shipping on the *Resolute* at New York City, and Acting Asst. Surgeon Domingo Lagomasino and Asst. Surgeon B. H. Kittrell, 1st Mississippi Volunteer Infantry, to go by shipping on the *Olivette* at New York City. To the Leiter general hospital, Chickamauga Park, Ga.: Capt. Geo. M. Wells, Asst. Surgeon U. S. A., from Ft. Ringgold, Texas, and acting assistant surgeons John A. Metzger and Ira C. Brown from Washington, D. C. To the general hospital, Ft. McPherson, Ga.: Major Royce D. Fry, brigade surgeon. To the general hospital, Ft. Monroe, Va.: Capt. Francis A. Winter, Asst. Surgeon U. S. A., and acting assistant surgeons Samuel P. Cottrell and Edward J. Mayer.

Nominations by the President.—To be Asst. Surgeons: 2d Volunteer Engineers, Edward J. Barrett; 3d Volunteer Cavalry, Edward S. Grigsby; 2d Volunteer Infantry, Charles Bruning, and 3d Volunteer Infantry, William A. Chapman.

Major George Franklin Shiels has resigned from the 8th California Volunteers to accept position as brigade surgeon.

Resigned.—Major George D. Ramsey, Surgeon, 69th New York Volunteers.

Disability Existing Prior to Enlistment.—The following, providing for the discharge of volunteer soldiers unfit for military service by disabilities existing prior to enlistment, was published from Headquarters of the Army, July 16, 1898. The necessity for this was developed by the examination of men for transfer from the line of the volunteers into the hospital corps of the regular army. So many of these men were found to be physically unfit for service that a general weeding out was considered necessary:

Information having reached the War Department that, notwithstanding the medical examination prior to muster in, men have been enlisted in the Volunteer Army who should have been rejected at that examination as unfit for military service, the attention of chief surgeons is directed to this subject as one of great importance. Systematic inquiry, with a view to eliminating such men, should be made in the various regiments and other commands by the medical officers on duty with them. A board of medical officers should be appointed in each division to carefully examine and make recommendations in each of the cases submitted by individual or regimental medical officers. In every case where discharge from service is recommended it should be seen that the certificates of disability embody a statement to the effect that the cause of the disqualification for the military service existed prior to the enlistment of the man, if such is found to be the fact. Department and corps commanders are authorized to order discharges on certificates of disability, such orders to be carried out by the regimental, independent battalion, battery or detachment commanders as the case may be. Such provisions of paragraph 140 of the Regulations as are inconsistent with the foregoing, are suspended during the war.

In the examination of certificates of disability for discharge, it is enjoined upon the chief surgeons, and others accountable, to observe that there is no conflict between the reports of company commanders, medical and other officers thereon, as to whether disability was incurred in line of duty, or not in line of duty. If any discrepancies exist in this particular, every possible means will be employed to harmonize the reports before finally forwarding the papers to the Adjutant General of the Army.

ORIGINAL ARTICLES.

A CONSIDERATION OF FOUR CASES OF EPILEPSY WITH REFERENCE TO CAUSE.

Presented to the Section on Practice of Medicine, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., July 7-10, 1898.

BY CHARLES S. BOND, M.D.

RICHMOND, IND.

It sometimes happens that a consideration of much worn subjects is profitable, and I therefore ask your indulgence for a few minutes to a subject, which is as old as any, in medicine, and which has profited as little as any, by the experience of past centuries. Undoubtedly the cause of this tardy progress is due in large measure to the multiplicity of irritations, which directly or indirectly produce the cortical explosions. Barring traumatic causes of direct influence, the study of peripheral sources of irritation is most interesting and fraught with the most lasting results. It is to this side of the study that the cases, selected out of a large general practice, are intended to be added.

□ *Case 1* is that of a little boy nine months old, who had his first epileptic seizures when but three months of age. The parents of this child are free from all influencing hereditary diseases; are not of neurotic temperament, and have neither of them ever manifested any tendency to epilepsy. Child cut two lower incisors at three months of age. Had no enlargement of head or abnormal curving of bones of spine or extremities. Has no organic disease of kidneys or liver. Was born under my care without instruments and being the sixth child, labor was easy. Child has never received any injury to head. Bones of skull do not overlap, nor are they in any way malformed. Child has never had any of the exanthemata, or other serious diseases, other than the one under consideration. So far as can be determined it has not inherited syphilis or tuberculous tissue. No intestinal worms were passed either before medication or afterward. It weighed about ten and one-half pounds at birth and increased its weight to eighteen pounds at the end of three months. Since this time diet has been limited and child now weighs about twenty-two pounds. It had never taken drugs of any kind until day of first fit, and had not been sick, in the belief of parents. Mother is a large, healthy woman, who had successfully nursed through babyhood four other healthy boys. Milk upon examination was found normal after child had first fit. Child was allowed during holidays to eat largely of candy and crackers for three or four days. At the end of this time the first seizure came on about seven o'clock in the morning, after a restless night. When called I supposed I had one of the numerous phases of convulsion so often noted in children. As I did not see this attack, was only permitted a description of it, which was to the effect, that child turned its head to right side, while in mother's arms, and began jerking the arms, then the head, and finally the whole body. Eyes were partially open, and eyeballs rolled upward with irregular motion.

At time of visit which was about one-half hour after seizure was over, which they said lasted about ten minutes, I found child still unconscious. Pulse 120. Temperature normal, skin moist. Pupil of eyes dilated, with balls turned upward. I advised a brisk cathartic of citrate of magnesia, and returned the

same evening to learn the child had gained consciousness in about one hour, was restless under influence of previous experience, and cathartic. Bowels had moved three times and stools contained large quantities of fermented milk and pieces of undigested crackers. Child had still no fever or other evidence of organic disease aside from symptoms detailed. During the day following child developed a condition of larynx which excited both curiosity and fear. Often, but not always, when the child would undertake to drink or cry, the larynx would be thrown into a tonic contraction which would last one-half minute and be accompanied by the most violent efforts at inspiration, the face becoming livid and very anxious until relaxation came on rather slowly and relieved. No loss of consciousness seemed to accompany these movements, yet within the same day child would often, some ten or twelve times, fix its eyes upon some object, or stare into space, without parents being able, for a short time, to attract its attention. These two evidences of petit mal have continued with more or less frequency for the past four months, while but four attacks of the heavier type have occurred, and these have been on two occasions accompanied by errors in diet by indulgence of parents. Am thoroughly convinced that the cortical explosions are induced by the toxic influence of fermenting food in the alimentary canal. It would seem to be the general effect, yet not being able to obtain urine from so young a child, it can not be definitely affirmed, that some end products might not have had also their normal lines of cleavage disturbed, with consequent leucemine poisoning. Limiting the diet, opening the bowels, and promoting good digestion have still further argued, by much improvement in the direction of this conclusion.

Case 2.—Boy 6 years old. Had his first epileptic seizure when seven months of age. As I did not see him until he was 4 years of age, I have been compelled to content myself with the history as given to me by the child's mother. These attacks as described by her were probably epilepsy, and occurred every month or oftener, at irregular intervals, and although constantly under a physician's care, grew worse both as to interval and severity of attack. When first seen in a convulsion three years ago the following memoranda were made: Face pallid, pupils dilated and turned upward, skin covered with profuse perspiration. No fever. Face was turned to right side, and muscles of arms in tonic contraction, thumbs being drawn into palmar surface tightly. Foamed at mouth and had bitten tongue slightly. Seizure lasted about thirty minutes, when it was succeeded by an interval of one hour of profound unconsciousness, after which he slowly regained a knowledge of his surroundings.

Father in this case has within the last four years, developed locomotor-ataxia. Is still able to attend to business. Mother at time of birth of this child had three uremic convulsions, and child was hastily delivered with forceps. No other hereditary tendencies have been transmitted to this child so far as can be learned from ancestors; child is very irritable and stammers in speech. Has never had any injury to

head, even including forceps delivery. He is about normal as to weight, active but impulsive. Eats heartily, and occasionally voraciously. Has no evidence of rickets. Has never had any of the exanthemata. Kidneys produce a normal quantity of urine, with urea and uric acid in proper proportion. The uric acid group, including xanthin and paraxanthin, was normal even following severe attacks. Fits occurred most often at night but occasionally during the day. Child had quite often during the day very unique pharyngeal contractions which were accompanied by a fixed gaze and a loss of consciousness. Radical errors in diet were often committed because of over-indulgent parents, and these errors were always marked by increased major and minor seizures. Conversely, the strict adherence to a limited diet of milk, without bromides, caused a very much longer interval, so much so that with aids to digestion there is hope that child may entirely recover from attacks.

Case 3 is that of a girl 17 years of age. Had first fit at age of 13, when she had three or four per day for an interval of four weeks. Menstruation had been established at 12 years of age. Mother healthy and no hereditary tendencies. Father now has paralysis agitans but otherwise family history is good. Girl is well developed. Weight about 110 pounds, height 5 feet, 4 inches. Has two healthy sisters, but no brothers. She has never had any serious sickness. Has had no injury to head. Can find nothing abnormal about uterus or clitoris. Has no habit of masturbation so far as careful watching can detect. In fact her history is negative except from causes that have their origin in the alimentary canal. Patient presented a model picture of gastric atony brought about in her case no doubt by prolonged habit of overloading the stomach. Physical examination and use of stomach tube disclosed a very greatly dilated stomach with consequently lowered powers of digestion, fermentation and retarded digestion being the inevitable result. This result was not mitigated even in bowels as particles of fermenting food were often passed in quantity per rectum. This was the condition at the time of first seizure. By the use of lavage twice per week and limiting the diet to one-half pint of milk every three hours for six weeks, the epileptic manifestations subsided. With but one exception this condition of passiveness continued for three years. In the meantime patient was gradually allowed a more extended diet, and after a time relapsed into old habits, when the seizures returned with renewed vigor. Most of them come on in the night, but several times she has fallen in the day time. Generally bites her tongue, and usually cries out upon the beginning of the attack. The same conditions exist as were found in the first instance, as regards stomach troubles.

I believe the source of irritation is also sharply defined in this case, and hope can be expressed in her case in my judgment. This last invasion has existed now about five months, with fewer attacks all the time. At first of period three or four attacks occurred daily while now only one a week. One curious fact which I think worthy of mention in this case was observed, and that was that when bromid of sodium was given it so disturbed the stomach that attacks were increased; at the same time she had aphasia, stammered, and could scarcely express her thoughts. This was after the use of forty-five grains per day for eight days. When drug was discontinued symptoms cleared away again. This was repeated three times with the same results, so that I feel confident of the observation.

Examination of urine in this case showed slightly diminished quantity of urea for twenty-four hours but no other abnormal products. Uric acid normal, paraxanthin only a trace, for four litres of water.

Case 4.—Young man 27 years of age. Family history good, on side of both parents. Has never been sick except during childhood. Has never received any severe injury. Was well born but has neurotic temperament. Has no organic disease of kidneys, liver, spleen, heart or lungs. Mentally quite bright and has no defects of special senses. Urine shows no abnor-

mal products in large quantities. Ten years ago while in school had first fit. After this had most of seizures at night about one or two months apart. About five years ago they had attained an average of one every two weeks. Has no petit mal, but says he can feel the approach of the attacks some time before they come on, by a peculiar nausea and hot sensation in epigastric region. This patient for six years had been under treatment of very competent specialists without relief. Bromid of sodium, and in fact all the bromids had been tried without limiting disease more than a short time.

A careful study of this patient four years ago, revealed the following facts, other than those before mentioned. Was very tender in region of epigastrium. Had dull, with occasional sharp pains in left side, augmented about one hour and a half to two hours after eating. Had a voracious appetite for food rich in carbohydrates, ate rapidly and failed to masticate his food properly, and went at once into active physical labor. A test meal, after one and one-half hours revealed a plus quantity of HCl, showing abundant remnants of the carbohydrates with absence of albumen and muscular fibers as revealed by the microscope. This condition was most marked at night, and it was at night that he had the epileptic seizures. I therefore, omitted all bromid salts, and recommended lavage before bed time—about two and one-half hours after evening meal. Used four drams of bicarbonate of soda to quart of hot water. Restricted diet to conform to these facts, using magnesia once a day to evacuate bowels. On this plan patient went five months without an attack. Interval of seizure has grown longer steadily, until it has reached nine months, and it is to be hoped that interval will increase indefinitely.

It will be observed that these cases represent great variety as to age. They include three boys and one girl, but they all have something in common, some form of irritation originating in the alimentary canal, causing, according to the best of belief, a cortical disturbance which in turn produces unconsciousness directly and reflex tonic and clonic spasm of peripheral muscular fibers. This analogy has been sought from a number of cases under observation, because of the stronger proof that such cases are to have upon the more extended knowledge of peripheral irritants in epilepsy, a fact which neither therapia nor many bright minds in the profession, are wont very rapidly to appreciate. Whether we believe in the causative influence of uric acid, or leucomain products from this group, or whether confidence is given to the total toxic effects of maldigestion, the fact still remains that a very strong relation exists between these products, and those cortical disturbances seen in the various forms, of so-called idiopathic epilepsy. Other sources of extrinsic irritation are numerous and have received due credit in most instances long since, while this more obscure field, and therefore all the more interesting one, still presents much for careful study, in the differentiation of such irritants. If the rationale of this phase of the disease is, therefore, that irritants from the digestive tract, through the blood, come in contact with the cortex, thereby evolving a constant or intermittent efferent current in like manner controlling the muscles, it would seem the highest service to such patients must come in the prevention of these products from entering the blood current. Under this view it is difficult to understand how the bromid salts can do more than palliate and thereby perpetuate an evil which is quite removed from the drugged cortex. Indeed, I shall venture the opinion, that in many of these cases, in the end the bromids do much more harm than good. In the first place by suppressing to a certain extent the evidence of an evil, which at that period is the most amenable to treatment, and in the second place by injury which these drugs often have upon the already diseased digestive tract, and lastly, the unusual effect which sometimes occurs to the cortex itself.

DISCUSSION.

Dr. C. G. STOCKTON—I have seen cases belonging to the class of cases the doctor has described so well; when I state that I state about as much as I can add to the discussion. I have seen cases of epilepsy in which the convulsions disappeared and there was no return. I have seen other cases in which the convulsions disappeared, but find only a temporary improvement, with a return of the seizures. My own opinion is that, first, many cases can be relieved by proper attention to the gastro-intestinal tract. Secondly, that in many cases there may be some improvement by aiding digestion. Thirdly, that there are many cases in which there is no improvement as far as can be found out.

Dr. LOCKARD of Colo.—I should like to call attention to some rational causes that existed in a case that I had recently. On the 12th of May last I was called to see a child, 2½ years of age; the messenger said the boy was about to die, for he was in convulsions. Upon arriving at the home of the child I found the child had epileptic seizures. I inquired into the causation or the history, and I elicited the fact that on the paternal side the great grandfather had been subject to epilepsy since childhood, he was then 64 years of age, and the attacks had begun in early childhood; when about middle age he moved to Colorado, when the attacks became less frequent. I further learned that one or two other members of the family, also on the paternal side, were victims of epilepsy. I therefore felt reasonably certain of the hereditary conditions being present. But to make sure that there could be no mistake in the diagnosis, and that it might possibly be a case of poisoning, because the attack came on so suddenly, the child being perfectly well all its life, I gave a hypodermic of apomorphia and I soon got the stomach contents. The attack had come on soon after dinner. The contents contained some blood that had been swallowed; nothing else was found. The child soon rallied, and the next two or three days was apparently as well as ever. It seemed to be a case of hereditary epilepsy. It was also discovered that the child had a phimosis, but because micturition was not difficult, an operation was refused. Here was found two pretty rational causes for the attacks. After the second day the child began to be restless and irritable; he would rouse from his sleep suddenly, and he grew gradually worse. The parents then called me in again, and I found symptoms of meningitis. On the following day there were more symptoms of meningitis, and in the course of twenty-four hours it turned out to be a typical case of tubercular meningitis—typical in every respect. The child grew worse, Cheyne-Stokes respiration appeared, and the signs were as typical as I ever saw. The child died three weeks after the epileptic attack. Here is a case in which we had two apparently rational sources to draw from. Yet the resulting subsequent course proved the attack to be due to tubercular meningitis; this should make us bear in mind that there may always be other causes of convulsions; we should especially look out for meningitis. I think in this case that the sudden development of tuberculosis brought on the attack.

Dr. TYSON—Doubtless all of us have had cases of epilepsy quite as difficult in explanation; some of them can be explained as Dr. Bond explains them, partly the result of reflex irritation and absorption of toxic substances. I remember two cases, both occurring in adults. One was in a girl, who had terrific convulsions until she was relieved of a tape-worm. Another occurred in a young man, who had convulsions for two or three years, and who was the victim of obstinate constipation. He had no attacks after his constipation was relieved. There are a few instances in which this condition is a result of Bright's disease; I am satisfied, though, that the reverse is true; that is, cases that are supposed to be due to Bright's disease are actually cases of epilepsy. An examination of the urine is important in these cases in order to settle any question. It is rare, but it does occasionally happen, that toxic substances and diabetes also may produce convulsive seizures of this kind.

Dr. ALLEN A. JONES—This paper is one of great importance and calls to mind some cases that I have had in which there has been not only the probability of auto-intoxication but occasionally a condition which gives rise to irritation of the stomach and to reflex disturbances. One case that I now have under my care and observation is that of a boy, aged 9, who had numerous convulsive seizures before I saw him. After going over the case carefully and eliminating some of the factors which might cause the convulsive seizures, I finally found a gastric catarrh with hyperchlorhydria, with gastric dilatation. After finding these conditions and placing the boy upon a restricted diet, and instructing the parents that the boy should not be allowed to bolt his food, and giving the patient HCl after meals and otherwise giving directions as to the hy-

gienic living of the child, the convulsions diminished in intensity and frequency until now, fourteen or sixteen weeks have passed, there is only the slightest evidence of disease. I never had a chance to see the case in a convulsive seizure. I am satisfied, however, that the boy should be classed as one having had epilepsy. He should be watched for several years.

Dr. SINME of Kentucky—I should like to state in confirmation of Dr. Bond's paper, that 95 per cent. of the cases of epilepsy, whether petit mal or grand mal coming under observation have been from reflexes from alimentary causes. This is true whether it occurs in infancy, childhood or in adults. Consequently I take the position that in the majority of cases the best remedy should be the regulating of the diet in regard to quality and quantity.

Dr. ANDERS of Philadelphia—If I understood Dr. Bond correctly he advises against the use of bromids in the treatment of epilepsy. In cases connected with certain causal factors it would be proper to drop the bromids and direct attention to the removal of the cause. In cases where the gastro-intestinal canal is disturbed, the question then might come up if it would not be better to treat the case in another way. Cases may occur in your practice in which the bromids are tolerated, where there is not the slightest evidence of gastro-intestinal disturbance, here it is certainly the first duty of the physician to continue the use of the bromids as the best means to ameliorate the attacks and the frequency of occurrence.

Dr. WEST of Galveston, Texas—I understood the gentleman from Kentucky to say that 95 per cent. of the cases of epilepsy were due to gastro-intestinal irritation; if that be the case why should so many of these cases be absolutely incurable?

Dr. ALLEN A. JONES of Buffalo—I should like to ask Dr. Bond the conditions of the eyes in the cases he reported.

Dr. ROBINSON of Illinois—I am much pleased to hear the paper read. It has been my experience that the diagnosis of epilepsy in children is not always easy; it is often very difficult, because we find so many convulsive seizures in children that are not epileptic. Last winter I was called to see a child, six weeks old, and could not determine the cause of the child's convulsions. A careful examination was made and I could give no reason for the seizures until I found small boils or abscesses upon the head of the child. I came to the conclusion that the child was pyemic; the abscesses upon the child's head had existed since birth and the blood was poisoned. The treatment directed to that condition was followed by recovery. The convulsions in this case were probably due to toxemia.

Dr. BOND of Richmond, Ind.—Four cases were presented with relief of the particular cause and it was shown that they do as well without bromids, if attention be directed to the alimentary canal by eliminating the products known to be in the canal. These cases do better without the bromids.

Of course there are many gentlemen who attend cases in childhood who see many cases due to various causes which are not epileptic in any sense of the word. Every one knows what cortical disturbances are; patients come to you with a history of having had epileptic seizures for a long time. As soon as the trouble is removed the patient recovers.

ON NATURE'S CURE OF PHTHISIS AND AN EFFORT TO IMITATE IT.

Presented to the Section on Practice of Medicine at the Forty-ninth Annual Meeting of the American Medical Association held at Denver, Colo., June 7-10, 1898.

BY JAMES T. WHITTAKER, M.D.

CINCINNATI.

Schlenker made a complete autopsy of 100 bodies of adults and children, subjecting the lungs, especially the apices, to thorough scrutiny, and examining minutely the mesenteric, bronchial and cervical glands. Of the 100 bodies, 66 were found to be tuberculous, and of these cases tuberculosis was the cause of death in 53 per cent., was of great importance in 6 per cent., and was latent in 41 per cent. of cases. These numbers are minimal because the examination was macroscopic, not microscopic, and because, even with the most critical examination by a special expert, concealed depots can be overlooked. A true estimate of the frequency of this infection can be derived only from tests with tuberculin. In this way, Kossel, one of Koch's assistants, who has devoted himself especially

to the study of tuberculin under Koch's personal direction, found that 2459 children at the Berlin Dispensary, tested as they came, reacted to the old tuberculin. Tuberculosis was evident in but four of these cases; in all the rest it was latent. The conclusion was that 40 per cent. of city children secrete tuberculosis in some part of the body. This test has already raised the ratio in cattle in various places from 15 per cent. to 40 per cent. No pathologist of repute will dispute the assertion that tuberculosis is present in two-thirds of mankind.

It is universally conceded that two-sevenths of mankind succumb to tuberculosis of the lungs alone. Including cases of intestinal, bone, joint and gland infection, it would be perfectly safe to raise the limit that minute amount which would bring the fraction to two-sixths. We will say, therefore, to be within the limits of perfect safety, that two-thirds of mankind are affected with tuberculosis and one-third dies of the disease. Therefore, in one-half of all the cases recovery is complete, or the disease is reduced to such quiescence as to become practically non-existent.

What is the process of cure in these cases? Nearly all the cases which have the benefit of altitude recover. There is something in altitude which in the first place gives immunity and in the second place arrests the progress of the disease. Individual cases recover also in all other regions of the earth, under all climates, with every kind of treatment, and under every variety of surrounding circumstances. There are conditions, therefore, under which patients affected with tuberculosis *must* recover, and others under which they *may* recover from the disease. What factors peculiar to altitude or common to all places may be adduced to account for these recoveries? An autopsy reveals in the cases the presence of adhesions, of nodules, of cicatrices and cirrhotic induration. The natural processes of cure would seem to be initiated, 1, by means which in some chemical way destroy the tubercle bacillus directly, as by the action of toxins or antitoxins, or 2, indirectly by sterilizing, immunizing or invigorating the soil.

Notwithstanding the great resistance of the tubercle bacillus, chlorin, carbolic acid, corrosive sublimate, the cyanides, and many other agents of great bactericidal power, destroy or inhibit the growth of the tubercle bacillus in various culture soils. None of these agents, however, is found natural in the body; therefore, they need not be considered here.

But we must bear in mind that phthisis or tuberculosis pulmonary as we see it, is not a simple, but is a mixed infection, whereby toxins are intensified through symbiosis. Certain micro-organisms antagonize, others intensify each other. The engrafting of the streptococcus pyogenes upon the tubercle bacillus produces toxins of higher degree of virulence than belong to either alone. One of the most essential factors in the treatment of tuberculosis is the prevention of mixed infection, especially with the streptococcus.

CREOSOTE.

Do we get any light as to natural processes from, or any successes with drugs? Creosote is the only drug which has held its place in the treatment of phthisis. Does it sterilize the soil and is there any such substance produced in nature? Unfortunately there is no good working theory to explain the action of creosote. Summerbrodt admits that a scientific explanation is still lacking, but maintains that creosote alters

the chemical properties of the juices of the body so that they no longer furnish a suitable soil for the tubercle bacilli, the colonies of which will not grow in it. Ludwig claims that creosote destroys the toxin of the tubercle bacillus, and Peter ascribes its virtue to the substitution of a curable hyperemia for a tuberculous hyperemia. Guttman found that in a solution of 1:4000 creosote exercises a marked inhibitory action on the growth of tubercle bacilli. It is certain that creosote in the dose in which it can be administered has no direct influence on the tubercle bacillus or on the streptococcus.

Cornet showed that the introduction of large quantities of creosote in the stomach did not prevent the development of the tubercle bacillus in guinea pigs. In the proportion of 1:100 it fails, after 24 hours' exposure, to destroy the tubercle bacillus in sputum. Sternberg found that a saturated aqueous solution does not destroy the tubercle bacillus in cultures in 12 hours. Trudeau observes that rabbits inoculated with tuberculosis and treated with creosote subcutaneously present the same lesions as control animals not so treated. Nevertheless the virtue of creosote is undeniable. It is admitted on all sides that creosote destroys all organisms that induce fermentation in the stomach without affecting the processes of digestion, and the virtues of creosote have been ascribed to the improvement of nutrition which sets in in some cases surprisingly soon. The remedy acts best in largest dose immediately after meals. Perfectly pure creosote is entirely void of toxic properties.

What would seem to lend support to the view that creosote acts by improvement of nutrition is the superior virtue of the carbonate of creosote, the so-called creosotal, the least irritating to the stomach of all the preparations of creosote or guaiacol. Pure creosotal has a syrup-like consistence and unless warmed is so thick as to drop with difficulty. As it is insoluble in water and only sparingly soluble in alcohol, it is best given in oil and milk. It exercises its best effects in doses of 40 to 60 drops dissolved in cod liver oil, or in warm weather suspended in half a glass of milk taken immediately after meals. My own experience confirms that of Gram, who finds after the use of large doses of creosotal a more rapid improvement in the general condition and of the local symptoms in a larger number of cases than after the creosote, and in a certain number where creosote fails. But as in the case of creosote itself, it may not be predicted in the individual case whether the effect will be good or not. As with tuberculin, it is necessary to try to find out. Neither creosotal nor creosote exercise any direct effect upon the streptomycosis, as neither agent will arrest or control acute hectic fever which depends upon an inundation by the streptococcus. Creosote may have some sterilizing properties, ill defined, but at the present time the conclusion is, subject to revision by enlargement, that creosote acts by improving the nutrition and thus invigorating the soil. We have no knowledge of any manufacture of creosote in the body.

TUBERCULIN.

The only natural agents of which we have any knowledge that are known to exercise an inhibitive action upon the tubercle bacillus are some of its own products, to-wit, the various so-called tuberculins which have been extracted from culture soils. These agents, which constitute the most remarkable contri-

bution to *materia medica* in modern times, give us the power of absolutely recognizing the disease in its very inception, and of nearly completely controlling it so long as the disease remains pure. There is nothing so subtle in medicine. Many obscure cases of failing health, of anemia, pleurisy, bone disease, are thus shown to be tuberculous, and tuberculin, further used in treatment, becomes a tonic in these cases of the very highest power. I have myself never seen any danger in the reactions of tuberculin and have never seen in any case a general reaction as severe as that which attends every vaccination. In either case extreme reactions are due to impurities, and it is interesting to know that the new tuberculin is now being prepared in solid form to obviate the evils of contamination. Tuberculin is produced in the bodies of tuberculous patients. It is present, for instance, in the fluid of pleurisy, which will give a reaction in guinea pigs. Doubtless many cases are naturally cured in this way. But for the most part the tuberculin is produced slowly and the body grows immune to it.

ARTIFICIAL SCLEROSIS.

Gross attempts at imitation of nature through the processes of cicatrization were made by Landerer with cinnamic acid and by Lannelongue with chlorid of zinc. Landerer set himself to work to convert a tissue poor in blood vessels and showing a tendency to caseation into a tissue rich in blood vessels with a tendency to form granulations and cicatricial tissue. After experimenting with a number of agents he found that cinnamic acid had the highest chemotactic properties, that is, that it would induce a migration of leucocytes into the necrotic tissue of tubercle. This process, he declared, is followed by the penetration of the mass by young blood vessels, the formation of young connective tissue, with subsequent shrinkage and contraction. In man there occurs also besides this shrinkage, calcification. Of 50 cases treated in this way 58 per cent. were reported cured, 20 per cent. improved, 4 per cent. unimproved, while only 9 per cent. of the patients died. Unfortunately, other experimenters failed to get such good results. The latest effort to secure leucocytosis by the ingestion of various nucleins, enzymes, etc., find also only individual support.

Lannelongue tried to induce sclerosis by the injections of the chlorid of zinc, finding after the introduction of this remedy an afflux of new tissue elements which infiltrated the periphery of the tuberculous mass, penetrated it somewhat and surrounded it with a fibrous wall which isolates the diseased tissue. These experiments fail, however, for the same reason as the surgical. They overlook the seat and center of the disease in the bronchial glands whence new colonies issue for new invasions of the soils.

EXPOSURE.

Nothing in art approaches the efficacy of nature in controlling tuberculosis of the peritoneum by exposure of that structure to the external air. Many theories have been proposed to account for the really wonderful results which followed this accidental discovery. But of all the theories offered, nothing is more satisfactory than the simple exposure to light and air. Many of the cases of typhlitis so happily controlled by simple incision are cases, not of appendicitis at all, but of tuberculosis of the peritoneum. Appendicitis is not as common as measles or mumps, as some of the surgeons seem to think, but tuberculosis is.

CARBONIC ACID.

An attempt at imitation of nature consisted in producing hyperemia in order to secure the effects of carbonic acid gas. As Traube showed long ago, patients affected with disease of the heart attended by hyperemia of the lungs enjoy a certain immunity to tuberculosis, as do also individuals affected with emphysema. Rokitsansky had remarked before upon the exemption from phthisis secured by certain forms of heart disease. Patients with deformed thoraces, hunch-backs, are also largely exempt from tuberculosis of the lungs, not on account of the limited expansion of the chest, but because the same amount of carbonic acid gas is distributed over a smaller surface. Workers about lime ovens are said to enjoy the same immunity for the same reason. Traube therefore proposed to treat the disease by developing carbonic acid gas in the stomach with hydrochloric acid and bicarbonate of soda. It will be remembered that Bergeon, at a much later date, attempted to secure the same effect by the injection of sulphuretted hydrogen gas into the intestine. Both observers reported good results, which, however, were not subsequently sustained. The latest application of this treatment is the method of Bier, which consists in inducing artificial hyperemia about tuberculous bone and joint disease by the application of an incomplete Esmarch bandage. But this method acts only temporarily and only in individual cases.

ALTITUDE.

Is there anything which acts in all cases? There is universal testimony to the effect that altitude actually cures phthisis. It is accepted, in fact, that climate, meaning for the most part the climate of altitudes, is a remedy so powerful as, if practicable in every case, to render superfluous every other treatment. We may ask ourselves, therefore, what are the peculiarities of the climate which control phthisis?

Altitude acts in various ways. First, by dryness. High air is dry air, and dryness is inimical to the growth of the tubercle bacillus. Second, by cold. On the average the temperature falls about 3 degrees for each 1000 feet of elevation. Cold favors dryness. It is also a stimulus. It increases the tendency to sleep, exemplified best in states of hibernation, during which there is little waste. Third, by sunshine. Tubercle bacilli are killed under an exposure to direct sunlight in a period varying from a few minutes to a few hours, according to the thickness of the layer exposed, and by ordinary diffuse daylight in six to seven days. It would appear from the analogies of photography as if the germicidal action of light is due to the increased oxidation. Fourth, by increase in the quantity of ozone, the natural purifier, which has in the minutest quantities enormous bactericidal effect. Fifth, by purity, as the air becomes more and more free of organic matter, including bacteria, as we ascend. Miquel found the air of Paris to contain 55,000 bacteria to every ten cubic meters. These bacteria decreased steadily with altitude until at the height of two and one-half miles they disappeared entirely. Sixth, by rarefaction, which is the most important factor of all. The air grows lighter and thinner as we ascend, until at the elevation of Potosi, Bolivia, 13,300 feet, it is only one-sixth as dense as at the sea. The rarefaction of the air leads to increased exercise of the heart and lungs and thus to continuous, even though unconscious, gymnastics. The

dyspnea, palpitation, vertigo, which attack the mountain climber, the cyanosis and unconsciousness experienced by the aeronaut at still greater heights, depend upon insufficient oxygenation of the blood.

POLYCYTHEMIA.

Now, as there is no elevation which man has ever attained in which the quantity of oxygen in the air is not more than sufficient for the wants of the body, it was for a long time difficult to account for these symptoms, which are sometimes embraced under the term "mountain sickness," in altitudes. The explanation was finally found in the phenomena of pressure. The blood corpuscles will take up oxygen only at a certain degree of pressure. Any great variation from this degree is attended with difficulties which are sometimes serious. Bert found that a pressure of fifteen atmospheres is fatal. On the other hand, the blood corpuscles will not take up enough oxygen under a greatly diminished pressure, and nature adjusts herself to this difficulty by increasing the number of blood corpuscles and diminishing their size. The curious fact is observed, therefore, that as the flora differ at different altitudes, so do the number and size of the blood corpuscles. It was Viault who first observed that the number of red blood corpuscles was increased one-half at the height of 14,000 feet in the Cordilleras. This fact has since been abundantly confirmed, so that at the present time tables are constructed showing the number of blood corpuscles at different altitudes, ranging from 4,974,000 at Christiana, to 5,752,000 at Zurich, 1,373 feet; to nearly 6,000,000 at Reiboldsgrün, 2333 feet; to 7,000,000 at Arosa, 6000 feet; and to 8,000,000 at the Cordilleras in Peru, 14,640 feet.

Here, now, is a clue which nature gives and which should be followed up. The specific value of altitude is therefore not merely exposure to outdoor air and sunshine, though by the so-called out-door treatment or porch treatment we imitate the methods and secure the virtues of oxygenation and insolation in the greatest possible degree in low levels. But the polycythemia is an accommodation to the lessened pressure, for the same increase in the number of blood corpuscles in animals may be artificially produced by confinement in a rarefied atmosphere. Thus Raynaud put a rabbit under a bell glass jar, taking the precaution always to have two jars that the animal might be transferred from one to the other for the sake of cleanliness, reducing the atmospheric pressure to an equivalent of an elevation of 9500 feet. The rabbit remained in this atmosphere a month and a half and came out fat and healthy. Examination of the blood showed it had absorbed 21 c.c. oxygen, while its fellows at sea level had absorbed only 17 c.c. This capacity of greater absorption of oxygen was obtained in four weeks.

May we imitate this process in the pneumatic cabinet? I made a number of experiments with men in this way, but obtained no favorable results whatever. But the pneumatic cabinet may in no way compare with mountain climate. In the first place, the stay must be necessarily short. In the second place, the individual becomes contaminated by his own exhalations, as the enclosed chamber necessarily implies a defective ventilation. The experiments made hitherto have shown no increase in the blood corpuscles or in the hemoglobin and still less that increase in strength which develops so rapidly in the mountain climate.

As the virtue of the mountain climate under a combination of all the factors found in altitude seems to depend chiefly upon the increase in the number of blood corpuscles, it occurred to me to try to secure this increase in a more direct way.

TRANSFUSION.

The transfusion of blood is as old as the history of medicine. Such extravagant ideas are entertained regarding the value of it as to have led to its abuse and abandonment altogether. But transfusion is one of those things that will keep coming up. It has been revived from time to time with various improvements in the method of use, but has become practically limited in our day to the treatment of hemorrhage and to poisoning by certain gases. Thus Stocker mentions the fact that the introduction of defibrinated human blood succeeded in rescuing a case, after artificial respiration, fresh air and Faradization of the phrenic nerve had remained without effect. The writer once succeeded in the same way in recovering a patient who had been bled *ad deliquum animi* under the hemorrhage from gastric ulcer. Arm to arm transfusion, as by the direct method of Aveling or by the indirect method of v. Ziemssen, by the aid of three syringes, has been rendered practicable in expert hands. But transfusion by the amateur is not without danger, and on account of the difficulty of obtaining blood at the proper time, is limited in use. Aside from the inevitable danger of coagulation, direct transfusion, even when most successfully practiced is sometimes followed by fever, which is looked upon as a sign of ferment intoxication (Heineke). Sometimes this ferment intoxication shows grave symptoms, bloody stools, tenesmus, even sudden death by asphyxia. The occurrence of dyspnea or cyanosis should interrupt the process at once until these symptoms disappear.

The difficulty, often insuperable, of obtaining the blood of man has led to the use of the blood of the lower animals. But there could be no question of the direct injection of the blood of lower animals into the veins of man. Landois showed long ago that heterogenous blood, that is strange blood, in the proportion of 20 per cent. of the original mass causes death on the first and second day, while less than 10 per cent. produces great weariness, diarrhea, dyspnea and a tendency to real hemorrhage, vomiting of blood, extravasations, bloody discolorations of the urine. Ponfick finds that hemaglobinuria constantly occurs even after the injection of 1 per cent. of strange blood into the vessels of the dog. Landois demonstrated further that strange blood corpuscles act like foreign bodies and are rapidly destroyed. The free hemoglobin colors the transudations and the urine, and forms cylinders in the urinary tubules, destroying the urinary secretion. The horse and ass, the dog and fox, different varieties thus of the same species, may exchange blood and it is only the blood of distant animals that may be regarded as heterogeneous, lamb's blood, for instance, in dogs and man. Von Recklinghausen reported a case of transfusion of lamb's blood in man followed by death in fourteen hours. In this case there was an exquisite amyloid degeneration of the liver.

In order to obviate these dangers v. Ziemssen recommended the subcutaneous transfusion. This author, who made a large number of experiments, found this method of value in the treatment of poison-

ing by gases and in certain chronic infections. He got his best results, however, in the treatment of scurvy and pernicious anemia. The subcutaneous transfusion has the advantage of being entirely free from danger. The blood thus introduced is speedily incorporated, so that the blood corpuscles actually multiply under its use. The method has, however, the great disadvantage of being so painful as to necessitate the use of anesthesia, a fact which soon led to its speedy abandonment. v. Ziemssen succeeded, however, in rapidly increasing the number of blood corpuscles in this way.

All these experiments were made with defibrinated blood. The blood was defibrinated both on account of the difficulty and dangers attending clot formation. The great desideratum was to secure a heterogeneous blood which could be introduced into the body with all of its ingredients quickly, safely, and pleasantly. In the ordinary process of defibrination the blood is stirred with rods, and the coagulum, which contains the bulk of the corpuscles, both red and white, is removed. But it was exactly the corpuscles which are wanted in the imitation of the natural process of polycythemia. It is the increase in the number of blood corpuscles in mountain air which enables animals, in spite of the reduction of pressure, to retain the oxygen of the blood in normal degree. This process of acclimatization is usually very rapid, the increase to the normal number of corpuscles being reached in two weeks.

Although it was not to be expected that corpuscles of heterogeneous blood or even of homogeneous blood could be bodily incorporated, it was fair to assume that the ingredients, especially the oxygen and the hemoglobin might be absorbed. I wanted to get also all the bactericidal properties of the blood. Fodor showed that fresh blood destroys numbers of bacilli, the serum more rapidly than the corpuscles as it is always seen that bacteria perish more slowly in the coagulum than in the serum. It was desirable also to have the blood of the youngest animals, as older blood loses its power to destroy bacteria. The immunity of sucklings may find its explanation in this way. The blood is therefore its own disinfectant inside the body. The increase in number of red blood corpuscles in animals increases the resistance and lessens the susceptibility to experimental inoculation of disease. It had, in fact, long been established empirically that anemic people are more easily disposed to infection than others. It was desirable also to increase the number of leucocytes. The process of leucocytosis marks a period of crisis by the liberation of antitoxins. The bactericidal property of the blood which resides chiefly in the serum is derived from the white blood corpuscles, in whose cells, according to Gärtner, all microbicidal power slumbers. The dissolution of the white blood corpuscles, under the action of bacteria liberates the antitoxin which destroys the bacteria. This bactericidal power is therefore weakened by hydremia, anemia, chlorosis and hemorrhage, so that the victims of these diseases, or puerperal women who have lost blood, are more disposed to infectious diseases and suffer elevation of temperature under slighter injury. Richter-Loewy finds that the introduction of agents into the blood which produce a hyperleucocytosis, such as peptones, cinnamic acid, or spermin, fortifies or protects the individual against infectious diseases, that is, that the increase in the leucocytes brings about a cure in cases in which

the result should be fatal without such treatment. It is a question if the enormous multiplication of leucocytes in leucemia be not a conservative effort to destroy the toxins of some malignant process.

It is a fact that hyperleucocytosis occurs during the development of malignant tumors and disappears after operative removal of the tumor. It is a fact also that leucocytosis has prognostic value in that the slight development or absence of it is an unfavorable sign. v. Jaksch goes so far as to recommend the induction of an artificial leucocytosis by the use of pilocarpin, antifebrin, etc. Certain tonics produce an increase of leucocytosis, tincture of myrrh, tincture of cinchona and other bitters (Hirt) further many ethereal oils (Binz) and the intense odors of fruits and spices (Pohl). The influence of perfumes upon neuralgia, headache, etc., may be thus explained.

Schattenfroh was able to obtain bactericidal materials from the polynuclear leucocytes after freezing and again thawing. These materials are probably excreted from the living leucocytes. Bordet too finds that the leucocytes furnish bactericidal matters to the blood. This conclusion is reached by comparing the effect of the serum of an immunized animal with the edema blood of the same animal. The edema fluid has no leucocytes and no bactericidal power. The blood has leucocytes and is strongly bactericidal.

Fischl of Prague, shows that the leucocytes contain a powerful protective agent against penetrating disease, as there was a marked increase of white blood corpuscles in animals that were saved from infections over those who died. The leucocytosis disappeared almost at the same time with the bacteria of the blood from the diseased animals. As the coagulum entangles most of the white blood corpuscles, it was necessary to prevent coagulation to secure their presence.

COAGULATION.

Coagulation sets in, as a rule, rapidly, within two to three minutes after venesection, and the process is complete in seven to eight minutes. The process of coagulation is closely connected with the life of the blood. The problems connected with it have received much study and are by no means settled as yet. The whole question is too complex for consideration on this occasion, when I have to speak only of means of arresting or preventing it. It may suffice here to say that the process is initiated with the changes characteristic of the blood of the cadaver, so that it may be said in a general way that the process of coagulation represents a beginning dissolution of blood and the prevention of it with simple means, may be regarded as the preservation of the life of the blood.

Coagulation is hindered by cooling, by increase of carbonic acid gas, whence it is that venous blood coagulates more slowly than arterial blood. It is prevented or delayed also by the addition of water, egg albumin, sugar and glycerin. A mixture of the blood with trypsin or with pepton stops it. Freund found that the presence of oil prevents the adhesion of the corpuscles, which he considers to give the impulse to coagulation. Thus blood received into a vessel from which oil has been poured does not coagulate, and coagulation does not occur when blood is stirred with an oiled glass rod.

The most curious fact in this connection is the prevention of coagulation by leech bites, discovered by Haycraft. The severe hemorrhage which is sometimes encountered after the application of leeches, is

only rarely to be ascribed to the hemorrhagic diathesis, but is much more frequently produced by the peculiar principle found in the front part of the body and secreted in the mouth of the leech. After the injection of the extract of the leech into a vein, the blood which flows from the carotid artery coagulates only very slowly at the end of an hour. At a still later period the coagulability of the blood becomes more normal because the substance which prevented coagulation escapes through the urine. Landois extracted this principle as a clear, slightly alkaline fluid and experimented with it on a large scale. The extract of the leech head does not injure the red blood-corpuscles, and it has been proposed to utilize the solution in small quantities in the prevention of thrombosis. v. Sahli, and associated with him, Aguet, showed that the thrombi usually formed by foreign bodies introduced into the circulation are hindered in their formation by the extract of leech. The possibility of utilizing this serum, especially in heart disease in which there are thrombi and infarctions, will depend upon further experiments upon animals. The exact nature of this principle is not established, though it is known not to be a ferment, as boiling does not destroy it. The poison of snake bites, especially that of the viper, contains the same principle.

The bite of many poisonous snakes, with the exception of the cobra, induces a permanent fluidity of the blood. The blood serum of different varieties of eels (Muränen), according to Mosso, 1888, delays or prevents the coagulation of the blood of warm-blooded animals. Snake bites poison the blood, while leech bites do not hurt it. The leech extract destroys the fibrin ferment without perceptible alteration of the blood, and the injection of it into the veins of a living animal stops coagulability without producing a toxemia. Anything like a long duration of the effect is hindered by the fact that the substance is speedily eliminated by the kidneys.

Leeches are sold with us at the rate of twenty cents each. Although the amount of material furnished by a single leech would prevent the coagulation of a considerable amount of blood (I have not yet determined the exact amount), the expense of securing leeches for copious or frequently repeated transfusion would prove an obstacle to their use. It is probable that if equally effective means had not been found, a larger demand might have secured supply at cheaper rates.

Various drugs and chemicals have the same effect. Thus Horne found that the soluble salts of calcium, strontium or barium delay or prevent the coagulation of blood in the proportion of one-half per cent. Barium are stronger than strontium salts, and these than lime. Chlorid of barium distinctly delays coagulation in the proportion of one-fourth per cent. Chlorid of sodium, chlorid of calcium in 0.07 per cent. and over, still more delay the coagulation of blood treated by the above-mentioned salts. It has long been known that oxalic acid and the oxalates prevent coagulation. I have found in my observations that five grains of the sodium oxalate would prevent the coagulation of a pint of blood. But oxalic acid is poisonous. The sodium oxalate as prepared for me by Mr. Fennel, contains oxalic acid in the proportion of 30 per cent. The largest fatal dose of oxalic acid recorded by Taylor is sixty grains, so that this small quantity is not dangerous. In fact, in

my observations no unpleasant effects of any kind were ever observed after the use of the sodium oxalate. I have been led to abandon this preparation, however, by the observation that the blood could be kept fluid by a number of agents, each of them constituents of the blood and therefore each of them articles of nutrition. These various agents are in common language common salt, the bicarbonate of soda and the sugar of milk. Thus a teaspoonful of common salt, two tablespoonfuls of soda and a tablespoonful of sugar of milk will keep a quart of blood fluid long enough for all practical purposes.

ALKALESCENCE.

The chlorid of sodium itself has a tendency to prevent coagulation. It also distinctly favors the hemopoietic process. The soda makes the blood additionally alkaline, and alkalinity favors additional bactericidal properties. It also favors osmosis. Alkalescence is one of the most important properties of the blood. It diminishes in anemia and cachexia and increases with improvement. The experiments of Calabrase showed that the alkalescence of the blood protects the body against the injurious effects of toxins. Alkalescence is connected with leucocytosis. Jacob holds it not improbable that the increase of alkalinity is due to a leucolysis. Bonne believes that increase of alkalescence increases resistance to the poison of bacteria. The alkalescence of the blood stands in close relation with carbonic acid gas. Krauss showed in unison with others that a high acidity and a remarkably low alkalescence is found under a great reduction of the CO_2 contents of the blood. The virtue of carbonic acid gas may find explanation in this way. Fever reduces alkalescence. Behring finds that the stronger alkalescence of the blood (corresponding to the greater amount of CO_2) of white rats furnishes immunity to milzbrand. So everything which has a tendency to drive out the CO_2 , or to fix it in combination, limits the bactericidal property of the blood. Thus there is after all scientific basis for the carbonic acid saturation, and effervescent drinks are something more than merely grateful drinks to fever patients. Krauss demonstrated that while the urine in health became alkaline after the exhibition of two to eight grams of bicarbonate of soda, alkalinity occurred in fever only after the exhibition of twenty to thirty grams.

v. Fodor found that the blood of rabbits has much stronger bactericidal properties after the injection of an alkali, and finally reached the result in his experiments that the organism reacts to certain pathogenic infections with rapid increase of alkalescence, which is followed by a greater or less reduction of it. If the infection is fatal, this reduction is pronounced and progressive; if it is not fatal, or less marked, the alkalescence increases anew and may exceed the original degree, the animal becomes more resistant to the bacteria which caused the infection. Neumann showed that an artificial reduction of the alkalinity of the blood lessened the resistance of the animals to infection, and Fodor demonstrated that the increase of alkalinity under the use of the mineral alkalies increased the resistance, so that it could be said that the degree of alkalescence in the blood destroys the susceptibility of animals to certain infections. According to Poehl, artificial immunity which is carried to great height by successive inoculations after the method of Behring, finds its explanation in the arti-

ficially induced leucocytosis with a simultaneous increase of the alkalescence of the blood. Fodor and Riggler in continuing their experiments showed that the alkalinity of various infections, including tuberculosis, increases under immunization, so that the alkaline co-efficient of the blood serum stands in direct relation to the degree of protection. Thus the degree of alkalescence has great practical value as showing the effect of the immunization, antitoxic treatment, etc., and as showing the power of the body to overcome infection. Fatigue diminishes this alkalescence and renders the individual susceptible to infection. Loewy and Richter showed also that the cooling of the body is attended by a simultaneous reduction of the leucocytes and of the alkalescence of the blood, and explain in this way the contraction of disease under what is called by the laity the process of "taking cold." What is more to the point with us at this time is the observation of Bonne, who found that the reduction of alkalescence under cold, remarked by Loewy and Richter, was attended with an increased coagulability of the blood. The fulminant character of certain diseases has been ascribed to a constitutional reduction of alkalescence.

Finally I added sugar, because the various sugars, especially the sugar of milk, all delay the process of coagulation. Besides, the sugar of milk has high nutritive value and makes but little demand upon the digestive juices.

The addition to fresh blood of salt, soda and sugar of milk adds nutritive principles, preserves the corpuscles, red and white, intensifies the alkalescence, prevents coagulation and prolongs the life of the blood. Thus the first part of the question was solved.

HOW TO INTRODUCE IT.

The next problem, the method of introduction, which seemed to be the most difficult, turned out the most easy. The nutritive properties of the blood are so well recognized as to be appreciated by the laity, and it is the custom in some countries, especially in France, but also to some extent in our own country, much wider than is commonly believed, to drink blood fresh at the slaughter houses. Sometimes patients stand in rows waiting their turn, cup in hand, as at mineral springs. The drinking of blood, however, is nauseating to many people. It is objectionable also because the blood coagulates in the stomach, forming a mass which may even fatally interfere with the action of the heart. Blood ingested in this way has, in comparison with other equally nutritious food, no advantage, but on the contrary much disadvantage. Recent studies go to show that the principles of blood are not disposed of in the stomach, but must be discharged into the intestine to be digested and absorbed.

It occurred to me, therefore, to introduce the blood directly into the intestine, and after some slight experimentation it was found to be perfectly easy to inject large quantities of fluid blood high into the intestinal canal. The injection may be made with the common fountain syringe or the bulb syringe, but is easiest and best effected by pouring it into the funnel and tube of the common stomach tube, which is easily pushed into the rectum to and beyond the sigmoid flexure. If the fluid is now poured slowly, a large quantity of blood may be carried into the colon so that much of it will pass the ileo-cecal valve to reach the small intestine. This injection is much

more bland and unirritating than the same amount of water, and is easily retained by all patients in the absence of any ulceration or deep congestion of the rectum. There is not the same desire, therefore, to discharge the fluid as in the case of a similar amount of water; not so much even as attends the injection of the same amount of olive oil. The injection is best taken at night with the patient lying upon the left side, and after the injection of it the patient should lie fifteen minutes further upon the back and fifteen minutes upon the right side, that the fluid may find its way throughout the colon.

I direct my patients to add a teaspoonful of salt, two tablespoonfuls of soda and a tablespoonful of sugar of milk to a pint of boiled water, and to pour one-half of this quantity into a clean glass jar, requesting the butcher to add to it one pint of fresh calf's blood. The fluid should be injected at once, or if this is not practicable, the jar should be put upon ice and the contents used within twelve hours. In no case should the fluid be heated, as heating favors coagulation and dissolution of the blood. This quantity should be introduced every night; in bad cases twice a day, morning and evening, and in all cases the bowel should be previously washed out with a simple injection of water. As a rule, to which there are many exceptions, the blood is entirely absorbed, so that often not even a trace of it is found on irrigating the bowel on the following morning.

The idea of using blood is so natural, the process is so simple and the results in many cases are so striking as to have led me to look up the literature to discover any former use of it in this way, and if so, the reason of its abandonment. For in all the recent studies concerning nutritive enemata, no mention is made of the use of blood. I find in the literature that Andrew H. Smith, of New York, first suggested and reported the use of *defibrinated* blood, in the *New York Medical Journal*, 1878, and that further reports were made in the Proceedings of the Therapeutic Society of New York and the New York Archives of Medicine of the same year. I learn further that A. Earnest Sanson made a report upon the use of blood clusters after the method of Andrew H. Smith, in the *London Lancet*, February, 1881. These were the first therapeutic suggestions. The report of Smith is based upon sixty-three cases, including thirty-eight of tuberculosis. In eight of these cases the blood could not be tolerated on account of irritability of the rectum or colicky pains. Ten cases remained uninfluenced by the treatment, or the improvement which showed itself had begun before the use of it. In twenty cases the good effect was distinct and was marked by increase of appetite and speedy disappearance of night sweats and diarrhea, lessening of cough, and especially by gain in weight. This treatment, however, was carried on in connection with the use of cod liver oil, brandy, expectorants and various remedies in address to the different symptoms. Nevertheless, distinct advantage could be ascribed to the injections, as after interruption of them the patient grew worse, but on resumption of them began immediately to improve and gain in weight.

The most striking results were obtained in cases of great impoverishment of blood. Eight cases of anemia of high degree were entirely cured. Five cases of dyspepsia from various causes experienced great improvement and were finally cured, including

one of chronic asthma. Two cases of exhaustion were markedly benefited, one after fistula and one after dysentery. One case of uncontrollable vomiting from ulcer of the stomach entered the hospital unconscious and apparently moribund. Clysters were given of pure blood while brandy and milk were given internally. The patient recovered consciousness completely on the next day, was soon able to take food into the stomach, and left the hospital cured in five weeks. The conclusion was that nourishment could be introduced in this way better than in any other, and that there was no danger in the method, though continued for weeks.

Hanks reported a case in which a patient who suffered from uncontrollable vomiting after hemorrhage from the uterus, was sustained by blood clysters until the stomach could retain its nutrition; Brown, a case of paralysis with threatening inanition in a child aged two years, in whom clysters of dried ox blood were used and perfect recovery was accomplished. Sansom reported two cases, one of gastralgia in a boy who could take no food, in whom there was retention of urine, blood and pus in the urine, inflammation of the ureter, probably from oxalic acid stone. This patient received four ounces of blood, at first once a day and later twice, gaining gradually in weight as the stomach recovered its tone. Another case of gastrectasia marked by extensive purpura, violent pain, vomiting and great anemia was recovered under the use of blood clysters twice a day, improvement beginning as early as the third day.

Möller in his report in the *Deutsche Med. Woch.*, Vol. vii, pages 45 and 46, communicates the experiments made by Mosler in the Griefswald Medical Clinic. He showed that while a part of the blood was rejected, a certain quantity was always absorbed. A woman aged 55, suffering with chronic enteritis, marked by great anemia, received every day for four weeks injections of five ounces of blood, the condition improving continuously. The number of blood corpuscles increased from 1,804,000 to 1,865,000. A second patient, who had twice suffered an attack of pneumonia, was now affected with extreme anemia from frequent nose bleed and hemorrhage from the bowels. This patient, edematous about the legs and face, with enlargement of the liver and albuminous urine, showed all the symptoms of anemia of the brain. Blood clysters, five ounces, were injected daily, the weight increasing from 119 to 124 pounds, the blood corpuscles from 960,000 to 1,136,000. Although in a third case the nutrition was sustained entirely in this way for one week, it did not seem to be determined that life could be supported indefinitely by these injections.

The experiments of Mosler were made with swine's blood, those of Smith, Sansom and others with ox blood. It will be seen that these observations and experiments were quite different from my own. In all cases the quantity was small, four to six ounces, and in all cases the blood was defibrinated. I used blood with all its ingredients, and instead of subtracting from it by the removal of any of its elements, I added to it principles of great nutritive value, salt, soda and sugar of milk, which served also the additional purpose of increasing the alkalinity, preventing coagulation, facilitating absorption, and above all things, prolonging the life of the blood. Further, the quantity which I used was four to six times as great as in previous observations, the easy retention of the

larger amount in the great majority of cases being due to the blander character and to the deeper introduction of the nutritive fluid.

In my experiments I have lost a good deal of time in determining the best agents for preventing coagulation, so that I am able to report upon but twelve cases of phthisis and one of apparently pernicious anemia. I make this statement, therefore, only as a preliminary report. In two of the cases there was considerable difficulty at first in retaining the fluid. In all the rest the blood was held without effort. The patients without fever or with but slight fever showed a continuous gain in weight, but patients with high fever showed no improvement, and in one case of severe hemoptysis, under the charge of my assistant, Dr. Malsbary, the number and frequency of the hemorrhages remained uninfluenced. In fact, the fear was entertained that the injection of blood sustained the hemorrhages, but no improvement followed cessation of their use. The most decided change was seen in the cases of anemia, one of which—a seemingly fatal case of apparently pernicious form—after failure with iron, arsenic, and later mercury, gained twenty pounds in three weeks under the blood clysters alone.

The cases of phthisis marked by anemia were the most benefited and the most rapidly, registering gains in several cases of two to three pounds a week. The bactericidal virtues I had hoped to secure were by no means so pronounced, but the gain in nutrition fully equaled expectation. I can commend these blood clysters as far exceeding in nutritive value any other as yet devised. They are also, as a rule, better borne.

SOME USUALLY OVERLOOKED PHYSICAL SIGNS AND SYMPTOMS IN CHEST DISEASES.

Presented to the Section on the Practice of Medicine at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-30, 1908.

BY NORMAN BRIDGE, A.M., M.D.
LOS ANGELES, CAL.

The tendency of the mind of the young doctor, and some times of the older one, is to look for the classical and typical changes in all chest diseases. He knows well what ideal bronchial breathing is; what râles are and the different sorts; what pectoriloquy, egophony, amphoric sounds and metallic tinkling mean. He knows flatness on percussion and dullness when marked; and cracked-pot percussion sound with open-mouth breathing. And if these or a combination of them are found in any case, diagnosis is supposed to be thereby relatively easy.

In our early studies we learn to look for these signs, and are disappointed sometimes when the symptoms have led us to expect to find them and we do not find them. Failing to discover them we sometimes wholly fail to detect other ample physical signs, that are however less prominent and pronounced. The descriptions in the text-books have given us these and similar classical signs as they are found in their perfection, and we are liable to dwell on them so fully that anything short of their ideal manifestation we pass over and hardly notice. This is one of the faults of our usual method of study which is to consider the sick from the standpoint of the classical description of the different diseases, and try to find the right picture to fit each case, rather than from the clinical standpoint

of the symptoms and signs which the patients as they come to us actually have.

In certain lung diseases, notably tuberculosis, it is of the greatest moment to be able to make an early diagnosis. Many a patient, who must otherwise die, could be helped if the diagnosis were made early, and before the different or any of the classical physical signs are completely developed. To do this we must invoke several aids and tests not usually thought of. We must learn to detect slight changes from the normal conditions, the first intimation of those variations of sounds in auscultation and percussion that progressively develop into classical signs. The doctor who examines his cases critically sees forty-fold more of them having these slight changes, than of those which show the ideal signs.

Pulmonary tuberculosis, fortunately for this study, is usually unilateral at beginning, and so we have early a normal side of the body for comparison. By examining the two sides critically, and comparing them with each other repeatedly, it is often possible very early to detect alterations that point unmistakably to lesions that are progressing. We perhaps find on one side a slight lessening of the force and loudness of the vesicular murmur on inspiration. Or there is a slight increase in expiratory sound at first without a particle of the quality known as tubular. Can we hear the expiratory sound better on one side than on the other? If so, there is an abnormal condition in one lung, either where the sound is louder or softer, of course always making allowance for the slight disparity in sounds between the two apices. Later, if the change progresses actual tubular breathing may be heard, at first with so little of the tubular quality that it can barely be perceived.

The two sides should be gone over everywhere carefully, and corresponding points of the two critically compared, to see if any anatomic region can be found where there is even a slight difference between them in: *a*, length of the inspiratory sound; *b*, intensity of the normal vesicular quality of that sound; *c*, length of the expiratory sound; *d*, intensity of this sound and the elevation of its pitch above what is normal; *e*, vocal fremitus on the uttering of words that cause an extreme degree of vibration, as *ninety-nine*, and *f*, the transmission to the auscultating ear of the ordinary voice and soft whisper. Râles should be searched for in deep inspiration with profound expiration and on voluntary coughing. Tuberculosis usually begins in a circumscribed region of one lung, and is often first seated in the bronchial mucous membrane. If there is any tendency to recovery, any conservative power, it soon causes a deposit of adventitious fibrous tissue (fibrosis) through contiguous lung tissue, which invariably changes the physical signs and in the way indicated, only a slight change being perceptible at first and the signs being most changed nearest the focus of the disease, and shading off toward normal sounds farther away.

Finding any of these slight changes we should carry our comparison of the two sides to other regions, all over the lungs, and find where they are most evident. That will be nearest to the focus of the tuberculosis if this disease is present. If a deposit exists in an apex, fibrosis will spread from that point. The back is the best region for comparison of the two sides. Listening over the lower zone of the lungs posteriorly the sounds are absolutely alike and normal on the two sides; as we rise step by step, listening over every

half-inch vertically and changing the stethoscope repeatedly from one side to the other we soon strike a zone, perhaps at the lower angles of the scapulae, where we can barely perceive that on one side the vesicular murmur on inspiration is a trifle less pronounced and the expiratory sound perhaps a trifle more so and longer than on the opposite side at the corresponding point. One inch higher up this disparity is, while apparently not more marked, yet slightly more perceptible, which means that it must be more marked. Above this level the difference is progressively greater; the vesicular murmur is, as we ascend, growing less and the expiratory sound greater, louder, longer and stronger, and soon higher in pitch. Perhaps near the spine of the scapula the expiratory sound is longer than the inspiratory, and is definitely tubular and has a pitch perhaps as high as the inspiratory sound. Over the seat of the deposit, if the bronchi are not closed by phlegm or otherwise, this tubular breathing is most striking, and is ideal if the deposit is extreme; at the same time the vesicular murmur on inspiration may be nearly gone. But if the deposit or thickening of the connective tissue is slight, the most pronounced change in the sounds does not reach an entire ablation of the vesicular murmur on inspiration, nor is there any ideal bronchial breathing, but only a slight increase in the loudness and length of the expiratory sound.

As the expiratory sound increases in loudness and rises in pitch there is always, other things being equal, a corresponding increase in the vocal fremitus over the region, as well as in the transmission through the chest wall of the voice in phonation and whisper. With patulous tubes these sounds increase in loudness if not always in distinctness, as the solid substance of the breathing organ increases in mass. For the interest of the patient it is in cases of just such slight alteration as here indicated that the signs are of paramount importance, that is, mainly in cases of incipient phthisis. This careful method of auscultation from side to side and the testing of the fremitus and voice transmission, should be made in all cases where there is a particle of question as to some disease of a lung.

Many things beside tuberculosis may cause a slight disparity between the two sides of the chest, and pleuritis is one of them and rather a common one. If the difference between the two sides is slight and uniform over the whole of both lungs at the back, and there are no other signs, then a former pleuritis is probably the cause. The disease may have occurred many years before, producing slight changes in the superficial portions of the lung, probably in the shape of permanent thickening of the connective tissue, whereby the vesicular murmur is a little reduced on inspiration and the expiratory sound is prolonged. The thickened tissue of a cured tuberculosis makes disparity of sounds between the two sides, but not a uniform one; the difference is greatest over the lesion.

In many cases of considerably advanced phthisis the physical signs are markedly reduced, especially the râles, by deep inspirations and failure to expire freely. The result of this is a dilatation of the bronchi and lung tissue to such a degree that the moving air does not disturb the phlegm to cause râles, and the otherwise marked bronchial breathing is nearly abolished. In a few incipient and slight cases this trick of many patients is quite enough to hide all the signs. Patients must sometimes be taught and induced to expire profoundly to enable us to detect fine râles in

bronchi of only moderate size. It is an impulse of many patients to make the chest large for the doctor to listen to; it is either an act of politeness or to show themselves at their best. They first increase the lung air contents enormously by expansion, then take in and expel but little air with each respiratory act, so that the residual air is greatly increased and the bronchi are distended, and the phlegm that lines them is not disturbed and so no râles result. Let a full expiration be made and râles at once appear. Failure to resort to this maneuver has several times caused an early diagnosis, that was perfectly possible, to be missed in a case of incipient phthisis confined mostly to the bronchi. Nor should one trial of this measure be regarded as sufficient in a doubtful case, but repeated similar tests should be made.

The diagnostic value of extreme expiration is not confined to the production of râles by the undisturbed flow of air through the narrowed air channels. Sometimes if the patient will voluntarily cough at the end of such an expiration râles will be most unexpectedly brought out that could not occur without it. This test should always be attempted in a doubtful case. The explosive blast of air may under forced expiration easily move some phlegm, creating a sound audible to the auscultator, when no amount of deep breathing could produce it.

The limit of possible expiration should be secured, with open-mouth breathing in making the test with the fingers or a soft hammer for cracked-pot percussion sound. This will often produce it to a slight degree when it could not otherwise be developed. I do not undertake to say amidst the doubt on this point, just what a slight cracked-pot sound always means in disease of a lung, but when it can be produced on one side only, and especially in conjunction with slight râles, even if both are made possible by the maneuver referred to, it certainly denotes some disease of the part, and that in beginning cases is important.

The average patient does not know how to make profound expiration. Tell one to do this and he will at first as likely take a deep *inspiration*. The human mind, save in the susceptible and very teachable and adaptive years, can not do a new sort of muscular evolution off-hand on simply being bid to do it. One must be taught. Profound expiration is such an act, open-mouth, normal breathing is another; and in our efforts at teaching them people are as amusing as they are in that other experience of doctors with them, when bed-patients are asked to turn over on their backs. Fully ninety-nine per cent. of them will turn themselves prone with their backs uppermost, or start to do it, before they discover their mistake.

In a lung with beginning tubercular deposit in the upper part near the larger bronchi, the vesicular murmur is sometimes lessened over almost the whole lung, except the part that lies directly above the deposit, and there is very little expiratory sound with little of the tubular quality and few or no râles, while the vocal fremitus is still moderate in degree and the percussion resonance is nearly normal, but there is reduced transmission of voice sounds. There seems no way of explaining such a state of things but by assuming a complete closure of some of the bronchi, by pressure from without or by thickening of their walls or by thick phlegm within them. For the lungs are full of air as shown by the resonance on percussion; there can be no great consolidation, and if tubes are only partially closed there is sure to be râles of some sort, and usually many of them.

Early in most cases of unilateral, localized tuberculosis, some aid to diagnosis may be found in the symptom, usually neglected, of greater cough during recumbency on the affected side. If there is much phlegm having a fair degree of fluidity, and the local seat of its formation does not reach to the lateral periphery of the lung, and usually in the beginning it does not, it is sure, when the patient lies on the bad side, to run down into the smaller bronchi by gravity and provoke cough. If he lies on the opposite side gravity carries the product into progressively larger tubes where it can spread out, its bulk lessened by drying, and adhere to the tube-walls without causing much cough often for many hours, even to the limit of a night. In the morning the activity of the patient and perhaps the taking of food and drink, induce a paroxysm or two of cough and the mucoid accumulations of the night are expelled. As soon as the lesion extends to the lateral periphery of the lung, or if it should happen to begin there, so that its tubes and perhaps its air vesicles are full of fluid this test will fail. But it must be rare that for this reason it would fail in an incipient case; it more often fails from the paucity of the secretion. It is not at all unusual for this symptom to be pronounced early in a case and exactly the reverse symptom be present later when the air channels of the periphery of the affected lung become full of muco-pus; and on rational grounds this is what we should expect. The cough then is least when lying on the diseased side.

A striking tendency to error in considering chest signs is shown in cases of fluid in the pleural cavity in little children. In a considerable majority of instances this condition is at first overlooked, as it is often missed throughout the whole sickness. This error is not confined to young doctors but comes often enough to veterans. It comes probably of the double mistake of supposing that the physical signs in children and adults are the same with given pathologic conditions; and in taking too literally in diagnosis certain rules which have grown into the literature and seem altogether rational, but which are unreliable and lead to many pitiable blunders.

Dulness on percussion is a sign in pleural effusions, but in small children there is little or no dulness over the lower part of the chest, especially on the left side; the gas in stomach and bowels almost completely masks this sign. If the pleural cavity is full to the very apex there is dulness, even flatness at the top, which by absence of dulness low down often leads to the erroneous theory of apical consolidation of the lung.

The books say, and it is a fatally false guide, that the intercostal spaces bulge. They do when the pleura is tense nearly to bursting, once in a hundred cases, not more. Why should such a misleading statement be perpetuated through generations of writings! Why not have said that the intercostal spaces are less depressible and more firm, and been correct and consistent?

It is well understood that lung sounds are not much transmitted through fluid: but over a child's pleural cavity full of fluid faint bronchial breathing is heard. This fact, with the absence of bulging spaces, leads many doctors to dismiss the theory of fluid in the cavity, although vocal fremitus is absent or greatly reduced and the heart is beating far to the right or left of its normal position. The change in the fremitus (if the bronchi are patulous) must mean fluid or air in the pleural sac, and the heart does not move

without assistance; yet we ignore these facts because we hear bronchial sounds or distant murmur, fail to find dullness in the lower chest zone, and the intercostal spaces do not bulge.

DISCUSSION.

Dr. E. FLETCHER INGALLS of Chicago—The paper which has just been read has many points of interest to many physicians and I think they can not be insisted upon too strongly. The majority of the points are familiar to most of us, but to the young physician particularly it is easy to point out discrepancies between actual facts and those laid down in the text-books. It is especially important in the early stages of phthisis, where the disease is localized in the beginning. There is a decided or a slight change from the normal if the disease is limited to a small portion of the lung and that is a grave sign. We must remember that similar changes occur in bronchitis and, not infrequently, in pneumonia. This should be taken into careful consideration before pronouncing diagnosis. In comparing the two sides the statement that the back is better than the front does not correspond with my observations. I understand perfectly well that we can get clearer sounds over the lower lobe of the lungs than elsewhere, but in comparing the two sides, in the majority of cases, you can get better results in front than posteriorly. You can count more upon the changes heard from in front. There is a disparity between the two sides in 50 per cent. of the cases. While the paper directs proper attention to the early signs, we should be especially careful that these early signs are not confounded with other signs which have nothing to do with tuberculosis. I see a large number of patients sent to me by other physicians where there has been an error in diagnosis in pronouncing the case one of tuberculosis. I have seen many lamentable cases where the patients have been told that they had tuberculosis and they were made miserable for life and driven to an early grave. I have in mind now two ladies, occupying high positions in society, who were condemned to die with tuberculosis; in neither case was there any tuberculosis.

A sign not spoken of in the paper seems to me to be of greater importance every year, and that is the pulse. A rapid pulse of 115 to 120 in a person otherwise well points pretty positively to tuberculosis. Bronchial breathing is practically found in all patients suffering from pleurisy, over the effusion, but not as continuously as over solid lung. In the text-books the voice sounds are represented as being present over the fluid. In not one out of fifty will you be able to get voice sounds over the fluid.

Dr. JAMES TYSON of Philadelphia—Dr. Bridge struck the keynote in speaking of pleurisy with effusion in the fact of diminished fremitus, which always means pleurisy with effusion. There is, however, one exception, which occurs in children with a purulent effusion as contrasted with serous effusion; sometimes there is an increase of fremitus. This is said to be the case, although I have never realized that such was so.

Dr. C. E. EDSON of Denver—I want, to add to the remark made by Dr. Tyson in regard to the rapidity of the pulse not only occurring in advanced cases, but in the incipient ones: the rapidity of the pulse is a sign which has made me very suspicious in many cases. It is not only the rapid pulse which makes me suspicious, but also the irritable pulse. It is the nervous irritable pulse of small caliber that makes me suspicious of the early stages. This is not only a diagnostic sign, but one of certain prognostic importance, particularly in cases in this high altitude. It is a pulse which does not slow down in a reasonable space of time. If the pulse continues to be irritable the cases do not do well in the long run.

Dr. BEGGS, of Denver—The paper is an extremely important one, especially to the younger members of our profession. I remember one statement made ten years ago by Dr. Glasgow, of St. Louis, Mo., which has always impressed me; it was that no man was capable of diagnosing incipient phthisis until he had examined one thousand chest cases. What he meant was, the diagnosis of the early cases. This diagnosis depends upon the alterations in the quality, and this is extremely hard for students—yes, medical men, too—to learn to recognize in the early stages. I have found that statement to be true to a certain extent in my own experience. I am not sure of my own ability to make an early diagnosis, although I have been practicing thirteen years. In cases of incipient tuberculosis there is an inconstancy in the occurrence of vocal fremitus. I have found many cases which have practically the same anatomic conditions present, in which the character of the vocal fremitus and resonance varies; and, even in the same patient this varies from time to time just sufficient to make vocal resonance a matter of doubt. I also find that I must agree that the front of the chest is better for comparisons than the back.

As regards pleurisy, I have in mind a case of a child 14 years of age, in whom the right pleural cavity was nearly filled with a serous effusion, as was proven by puncture; in this case there was no bulging, and the measurement of the chest showed no difference between the two sides. And, so far as we could detect, there was no difference in volume in the two sides of the chest.

There is another sign which has given me more trouble than any other, which is mentioned in most text-books, and that is the *muscularis sussurus*; this has been to me a source of error in making diagnosis. This, too, is a sign that every student should have his attention called to.

Dr. BRIDGE—As I stated at the beginning of this paper, I intended to call attention to a few of the possibilities and likelihood of error in the diagnosis of chest diseases, particularly on the beginning of such diseases as phthisis. I should have made mention of the errors which might occur on account of the muscular action; this is a source of error and great trouble to young practitioners in listening to chests, where particular care should be taken to place the muscular fibres of the chest wall at rest. Here muscle tones are produced by contraction which would interfere with intra-thoracic tones if one be not careful.

It is possible that I did not make myself sufficiently well understood in speaking of comparing the two sides of the chest. In the beginning of phthisis at the apex, I have been better satisfied with an examination made from in front of the chest. Slight fibrosis begins above and extends downward, and frequently this fibrosis has so far extended as to interfere with the accuracy of this examination when made from in front. Then, too, you do not have confused condition of the heart sounds as in front. If you find that there is evidence of fibrosis extending below the fissure between the two lobes of the lung posteriorly, it is a very strong evidence that there is a lesion of considerable consequence existing above it. Another point I wish to emphasize is that the patient should be made to expire profoundly. I can mention many cases during the past two years where the diagnosis could not have been made of incipient phthisis without this fact being known.

In answer to Dr. Tyson I would simply say that I do not recall any instance where the tactile fremitus from the voice was greater over the accumulation of pus than over the opposite side.

I am amused at the statement made that one should examine one thousand cases of chest diseases before one is capable of distinguishing the slightest changes that occur in incipient phthisis. Practically that statement is true, though I do not believe that this is necessary.

ANEURYSM OF THE CONCAVITY OF THE TRANSVERSE ARCH, APPEARING EXTERNALLY AS A LARGE TUMOR IN THE REGION OF THE HEART.

Presented to the Section on Practice of Medicine at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY H. W. McLAUTHLIN, M.D., AND W. N. BEGGS, M.D.
DENVER, COLO.

Charles M., aged 52 years, musician, entered the Arapahoe County Hospital, Denver, March 9, 1898. His mother died of cancer, at the age of 70 years, and a sister of his mother died of phthisis. He had been given to dissipation, contracting syphilis when about 20 years old, and he was addicted to drink. He had contracted gonorrhea several times. During the last fifteen years he had had some rheumatism. He said his present trouble commenced four months before, with a bad cold accompanied by a severe cough, at which time a swelling appeared in the left chest, which had gradually increased.

The tumor had been tender and attended by shooting pains, moderate in character and confined chiefly to the region of the swelling. About two months before entering the hospital he became short of breath and this had increased so that he could with difficulty move about. He had coughed considerably and expectorated freely. His appetite had continued good but he was inclined to diarrhea. He had lost about twenty pounds in weight during the four months. He had also had some difficulty in swallowing.

Physical examination.—Patient is of small stature and stoops. He appears apathetic and weak. His memory poor. He answers the same questions differently at different times. Scars, apparently syphilitic, are abundant on legs and back. A tumor, the size of two large fists, on the left side of the sternum, extends from the lower border of the second rib to

the upper border of the seventh rib, and laterally from the center of the sternum to the middle of the axillary region. The tumor is firm to touch, but pulsates distinctly under the fingers, more especially at the base. No distinct bruit is audible. The position of the heart can not be determined, although the sounds are distinctly audible in the interscapular region and throughout the right side. In the left axillary region, just below the tumor, a systolic murmur is audible; flatness exists over the whole chest. The respiratory sounds are feeble and fremitus is absent, except in the upper part near the spine, where the breathing is bronchial with coarse râles. The right side shows exaggerated respiration in spots, with moist râles, the last being more abundant in the lower back. There is some edema about the ankles and the eyelids show distinct puffiness. The pulse averaged about 90 per minute; respiration, 39. In the right radial artery pulsation is scarcely perceptible, in the left it is present but extremely weak. Pulsation in the carotids is apparently equal. There is no tracheal tugging. The right pupil is larger than the left, the latter being smaller than normal, accompanied by some ptosis. But convergent strabismus in the right eye, the patient claims, is of much longer standing than the tumor. Slight hoarseness is present. Urine analysis negative.

He became progressively weaker. His temperature varied from 96 to 100, being below normal more than half the time. The tumor continued to enlarge perceptibly in every direction. On March 26 it is noted as extending from the clavicle to within four inches of the lowest rib, and laterally from the posterior part of the left axillary space to a point two inches beyond the right border of the sternum. The surface measurements were, vertical ten inches, transverse thirteen inches.

Dr. E. J. Rogers, the attending surgeon, saw the patient in consultation soon after his admission. A number of other physicians, especially Drs. Eskridge, Whitney and Sewall, made careful examinations. Dr. Rogers, by the exploring needle, withdrew a small amount of straw-colored liquid from the left pleural cavity. It was not, however, deemed wise to withdraw a considerable amount of fluid, although doubtless present, as it would tend to interfere with the established resistance hitherto offered to the advance of the tumor in certain directions. About ten days before death a reddened appearance of the skin at the summit of the tumor was noticed, as if the skin were about to ulcerate. A day or two later blood began to appear at this place, the most of it clotting as it appeared on the surface. It continuously stained his clothes. On several occasions he had requested the loan of a knife from neighboring patients, and he was put under more careful watching, as a mild delirium became manifest.

Early on the morning of March 28 he became quite suddenly and extremely distressed for breath. He complained of severe pain but could not locate it. He received temporary relief from one-quarter grain of morphia, hypodermically; about six hours afterward he began struggling for breath, tearing at his throat and was unable to speak. He conveyed the idea to those around him that his throat was closing up. There was apparently spasm of the larynx. Respiration ceased about thirty minutes later.

Postmortem examination by W. N. Beggs, M.D., four hours after death. It is the body of a middle-aged, rather emaciated, man. Rigor mortis is established and livories are present in the dependent (posterior) parts not subject to pressure. The eyes are dulled. Projecting from the left thorax is a large, almost hemispheric tumor. It extends from the left anterior axillary line to one inch to the right of the sternum and from the clavicle to the seventh rib. It is rather moderately firm to pressure. Over the anterior surface, including the area of the nipple, the skin is eroded and covered with dried, clotted blood for an irregular ovoid space two by one and one-half inches in dimensions. In dissecting away the skin over the tumor it was found that as this eroded area was approached the skin became progressively thinner, the subcutaneous tissue disappearing entirely and the cutis vera becoming so thin that, although great care was used, it was impossible to avoid invading the tumor itself. This having been done a very considerable amount of cruror was expelled and it was found that the tumor was saccular, communicating with the aorta. The eroded distal extremities of the second and third ribs extended into the cavity from the left and the fourth and fifth ribs were imbedded in the cavity, both being eroded, chiefly on the upper edges and under surfaces. The left edge of the sternum was eroded to a depth of about one-half inch, extending from the attachment of the second to the fourth ribs, the costal cartilages of which had entirely disappeared.

The pericardial cavity was entirely obliterated by adhesions of slight degree of firmness, not entirely recent, however. The heart, small, was turned to the right on its axis, the left

ventricle turned toward the front. The heart muscle was pale, flabby, rather friable, and of a uniform, diffuse, slightly yellowish cast. Death had occurred in moderate diastole and all the cavities contained a slight amount of mixed blood clot. The valves were normal. The ascending and transverse portions of the arch of the aorta were considerably dilated and the inner surface was wrinkled and freely dotted with irregular, yellow, very slightly elevated patches (atheromatous). At the concavity of the arch, beginning one and one-eighth inches above the upper margin of the semilunar valves, was the opening of the aneurysmal sac. This was eight and one-half inches in circumference. The sac was directed first downward and forward, then forward and upward, compressing somewhat the left bronchus, although there were no traces of erosion therein. Externally to the bony thoracic wall, the wall of the aneurysmal sac seemed to be composed of the soft parts of the thoracic wall.

In the right pleural cavity there were numerous, firm, old adhesions throughout. The right lung presented no peculiarities except a slight amount of emphysema. The left pleural cavity contained one and one-half quarts of a clear amber-colored fluid. The left pleura was much thickened and opaque. The left lung was very much compressed and consolidated, and contained no air, portions of it sinking in water. On cut surface it was of bluish-gray color, mottled with very many rounded and triangular-shaped patches, slightly elevated above the cut surface, varying in color from gray to yellow and in consistency from moderately firm to almost semi-fluid, the latter being characteristic of the yellow patches.

The liver was of approximately normal size. The upper surface was granular and covered with numerous shallow, richly-stellate scars. On the cut surface it was slightly granular, with distinct lobular markings, mottled dark bluish-red and yellowish. The splenic capsule was much thickened and opaque, white in color. On the surface were a few shallow stellate scars. Otherwise the spleen and the other organs not mentioned presented no peculiarities of special interest here.

A peculiarity of this aneurysm is the location of the external tumor, the usual place being beneath the sternum, below the right or left clavicle or in the back. A review of several authorities has failed to disclose so large an aneurysm, similarly situated. In case No. 150 in Hayden's work, the aneurysmal tumor extended from the level of the second to the eighth dorsal vertebra, occupying the position of the left scapula, which was displaced backward and outward. It was hemispheric and measured nine inches in the transverse and fourteen in the vertical diameter.

Differential diagnosis.—What were the signs and symptoms during life favoring the diagnosis of aneurysm and what other diseases should have been considered? The age of the patient, the history, the signs of syphilis, together with a pulsating tumor of the chest and pressure symptoms would certainly strongly suggest thoracic aneurysm. Yet the pulsation was nowhere strong, although toward the base a forcible and expansile pulsation was felt. Da Costa's most emphatic sign, viz., the presence of "two points of pulsation in the chest, two hearts apparently, each with its own distinct beat, its own distinct sounds," was absent, as the tumor included the ordinary cardiac area and the real location of the heart was not ascertainable. The absence of a thrill and of a murmur from the tumor is more corroborative than essential to the diagnosis, according to most authors, the number and solidity of clots in the tumor causing the variations in the signs to be derived from auscultation.

A pulsating empyema is said by all authorities to occasionally simulate aneurysm, especially when a pulsating tumor is situated in the region of the heart. In the case reported, physical signs of fluid in the left chest were present, viz., flatness, with absence of respiratory sounds and lack of fremitus. The tumor in this case was, however, enormously large for an empyema pointing externally. Moreover, the tumor was firmer and the pulsation more expansile than

would be expected in empyema; neither was the pulsation disseminated over the chest; unmistakable pressure signs were also present. The needle showed the fluid in the chest to be non-purulent.

The following case of pulsating empyema is reported in Stokes' work on the "Heart and Aorta":

The heart was displaced far to the right. "Each stroke of the misplaced heart produced the most extraordinary diastolic pulsation of the whole left side. The bed was shaken at each beat of the heart, and the patient's sleep interrupted by the vast and violent throbbing of the side; yet the force of the heart did not seem much augmented. There was no appearance of any external pointing of the contents of the sac."

Solid tumors of the chest.—Sarcoma, lymphomata and lymphadenomata are infrequent and tend to grow inward rather than outward. Cancerous growths are more frequent. If such a growth projects externally and pulsates, the symptoms and signs may simulate an aneurysm with rather firm clots. The expansile force is usually, however, much less distinct. The adjacent glands of the axilla and neck are often enlarged. The veins on the side of the thorax affected are more apt to be distended and especially, according to Hayden, varicose. The amount and character of pain is unreliable as a differential symptom. It should be noted in passing, however, that the degree of pain in this case was far less than would be expected in either an aneurysm or a solid tumor as large as the one under consideration. It is possible that he may have previously had more pain, but failed to recall the fact owing to the weak condition of his mind. It is more likely that pain was not prominent on account of the pressure of the tumor being outward rather than inward. The general health is usually poorer in cancer. In this case the general health was poor, but the other conditions could account for it. Osler and other excellent authorities speak highly of the diagnostic value, in aneurysm, of tracheal tugging, first mentioned by Oliver. On the other hand, Wood and Fitz state that Grimsdale considers the sign of little positive value, "since he found it in 16 per cent of a number of persons free from aneurysm and examined with reference to its presence."

Mediastinal abscess.—The size and location of the tumor, the character of pulsation, the degree of pressure symptoms and the character of the temperature would all tend against this as a probable diagnosis. Nevertheless, although there was a general expectation to find an aortic aneurysm at the postmortem, that expectation fell considerably short of being a conviction in the minds of those who had examined this patient the most carefully. The fluid in the pleural cavity, being clear, thin and non-fibrous, was probably due to pressure. Osler speaks of aneurysm from the lower or posterior wall of the arch compressing a bronchus, thereby producing bronchorrhea, gradual bronchiectasy and suppuration in the lung—a process which by no means infrequently causes death in aneurysm, and a condition termed at the Montreal General Hospital "aneurysmal phthisis."

Pepper speaks of an irregular type of fever in such cases, as occurred in the case here reported, and that chills and sweats may occur, more strikingly showing a septic process.

Lebert, who analyzed a large number of cases, found that the average duration of life after the first distinct symptoms of thoracic aneurysm was from

fifteen to eighteen months. A number of cases, however, are on record where life was prolonged for several years, and in a few for even ten years after an external tumor had appeared. In Hayden's analysis of sixty-eight cases, death occurred from rupture of the aneurysm in twenty-six instances. In only one of these twenty-six was the rupture external. Nine of the sixty-eight cases died from asphyxia. In the case reported here death would probably have occurred in a very short time from external rupture.

In reviewing this subject one is struck with the fact that hemorrhage from aortic aneurysm is far from being always fatal. Slow oozing or even quite severe and repeated hemorrhages, if there are intervals in which to recover from the immediate shock, may extend over a considerable time. Osler reports a patient who had "several brisk hemorrhages and who died four years after, having in the meanwhile enjoyed average health." Where there is an external tumor signs are apparent before rupture occurs. Stokes relates the following case, in which there was an external tumor in the lower sternal region which had caused absorption of the bone. There had been discoloration of the skin, followed by signs of sloughing, "so as to display what seemed to be the outer surface of the coagulum of the aneurysm. At each systole of the heart this coagulum moved outward, so as to close up the orifice in the skin and then receded during the diastole. After some days the coagulum gave way and a deluge of blood poured out. Immediate death would have followed but for the presence of mind of the nurse, who, on the instant, snatched up a cotton apron and stuffed a portion of it into the opening of the chest." The patient lived many days in good health and spirits, his life, so Stokes says, "depending on the precarious support of a plug of cotton rag which at every stroke of the heart appeared on the point of being forced out of its situation. The result was of course fatal."

Osler says that spontaneous cure is not very infrequent in small sacculated aneurysms of the ascending aorta. In many of these cases, the disease has been unsuspected during life and the obliterated sac found accidentally at the postmortem. Wood and Fitz state that aneurysms of the arch of the aorta "are always a source of danger and usually prove fatal, although they may exist for years. Their progress may be checked for a long time by the formation of thrombi, but the process of repair is always incomplete, and it is doubtful if any true aneurysm of the arch large enough to produce symptoms has ever been healed."

About ten years ago a patient died at the County Hospital here whose physical examination gave dullness over a portion of the chest, which, together with other signs which have escaped my memory, could not be satisfactorily explained. At the autopsy we were surprised to find the remains of thoracic aneurysm, the laminae of organized fibrin showing beautifully.

THE PATHOLOGIC ANALOGY OF BRIGHT'S DISEASE AND SYPHILIS.

BY W. H. WHITEHEAD, M.D.

ATLANTA, GA.

First having my attention called to the efficacy of specific treatment in a case of albuminuria, in which I gave the mixed treatment of potassium iodid and

mercury bichlorid for specific trouble, I was greatly surprised to see the albumin disappear, instead of its being increased by the supposed irritant properties of the iodid (as I had been taught it was "hard" on the kidneys), and was led to make a series of experiments in an effort to discover the *modus operandi* of this mixture, and whether it was the iodid or the mercury that produced the result, also, was the remedy only applicable to specific kidney lesion, or was it a remedy for the condition which we know as Bright's disease, but which I prefer to call arterio-sclerosis renal, as this term conveys some idea of the pathology of the condition.

Some years ago I was resident physician to a famous lithia springs, the waters of which are highly extolled for "all kidney and bladder affections." This modest claim brought many sufferers to "Mecca." Some were benefited remarkably, but I saw no authentic cure of Bright's, though many were greatly benefited in health, feelings, etc., and the albumin diminished notably. This was due to the large dilution of the urine, the increase in volume, and consequent removal of a larger per cent. of deleterious matter.

While at the springs I also had many syphilitics under my care, and to one of these cases is due the present series of experiments I have made, and am making, in regard to the treatment of albuminuria with antisyphilitic remedies, mercury and the iodids. The case that first claimed my attention was one of chronic syphilis, fifteen years after the initial lesion, and was then suffering from intense pains in both tibiae, and orbital pains. These pains came on at sundown, lasted all night and went away early in the morning, leaving the patient exhausted from suffering and terrific night sweats. It was a sad prospect, and to add to the dilemma, his urine was "loaded" with albumin. I made no quantitative test, but upon boiling in a test tube, the urine became gelatinous. The patient had been to Hot Springs, Ark., twice, with some relief each time, but soon relapsed. The physicians there told him his trouble was not specific but malarial, and gave him arsenic, iron, quinin, *et al.* He also took some baths and "rubbed some mercury" while at Hot Springs. I do not remember now whether he was instructed to do this by his physician, or whether he did it to keep from appearing odd.

At this time I was passing through the stage of evolution professionally, best called the electric craze. I tortured this poor man for weeks by applying galvanic electricity to his exquisitely sore shins and frontal region. Usual result. Having my suspicions aroused by the nocturnal recurrence of the pains and previous history of syphilis, I told him I thought a trial of antisyphilitic remedies was warranted. He consented readily, but there was that albumin, and the old idea of potassium iodid being hard on the kidneys.

But something had to be done, as the resident physician is supposed to be equal to all emergencies, at least to the keeping of all corners as long as possible, so I gave the regulation mixture:

Potassium iodid.	3 iiss	80
Bichlorid mercury	gr. vi	72
Aqua qs. ad to make	3 iv	130

M. Sig.—20 drops t. i. d. in half a glass of sweet milk after meals. Increase as directed.

In this mixture he received about fifteen grains of potassium iodid and about one-sixteenth grain of bichlorid in each twenty drops. This dose was in-

creased one drop daily until he was taking thirty-five drops three times a day, or about twenty-five grains of potassium and about one-ninth of a grain of bichlorid. At this time ptyalization caused the remedy to be suspended for a while, and on resuming it was given in fifteen drop doses t. i. d., increased as before. I will not dwell on the syphilitic feature of this case, as all such is ancient history. It is sufficient to say that all pains, night sweats, etc., disappeared within one month, and that under a continued and varied course of treatment extending over two years, he was thoroughly restored to health, gaining over sixty pounds in this time.

The only connection between all this, which happened years ago, and the present paper, is the above mentioned albumin. Being solicitous on account of the fallacious idea believed to be medical knowledge, and having heard some one say, or read that some one did say, "iodid of potash was hard on the kidneys," I often spoke to others of the danger of giving large doses of iodid of potash on account of the kidneys, and they, like myself, said "yes, yes, it is very dangerous." All had heard or read the same fallacy, for it is a fallacy, pure and simple. So, when I examined the urine of my patient, who had albumin, and whom I had put on the dangerous iodid, and found no increase of albumin, but on the contrary not near so much as I had found on the previous examination, I said, syphilitic albuminuria, gumma of the kidneys, fortunate thing, all syphilitic, will get well, and so he did; but I came near losing what I believe to be a grand truth. It passed me like a ship in the night. I thought the albuminuria was due to syphilitic disease of the kidneys, and hence the result. Today, I believe this the true and rational treatment for the condition we know as Bright's arterio-sclerosis renal. If the therapeutic test is worth anything, one of two things is true: Bright's disease is of syphilitic origin and demands syphilitic treatment, or the pathologic condition of arterio-sclerosis and cell infiltration that is present in both diseases demands the same remedies: witness the absorption of immense gumma, or the magic healing of old syphilitic rupia, to say nothing of the remote neuroses and circulatory lesions, even mental equilibrium being restored by specific treatment, when such conditions are truly due to syphilitic processes.

There is nothing strange or occult in the action of these drugs; it is simply the eliminating qualities of them. I do not know just how the thickened walls of the delicate arteriole and capillaries are absorbed, their elasticity and contractility restored, their circulatory functions renewed, and even the necrosed material absorbed or washed away by the renewed life current; but I know that this very thing is done when a syphilitic sore is healed, or a gumma is absorbed by the intelligent use of mercury and the iodids.

If then, we admit the striking similarity in the pathology of syphilis, and the disease process known as Bright's disease, why should we marvel if the same remedies are applicable to the same pathologic condition, even though etiologically different, which is not proven.

I have no table to submit, no ax to grind. I have applied this theory now in many cases of albuminuria, only one, the first, having any personal history of syphilis. In all of them the albumin is diminished or disappears altogether in from thirty to sixty days; recurring in some, to again disappear under the same treatment. In some it has not recurred at all after a

lapse of years. I have used the proto-iodid in one case along with potassium iodid. Results the same. I have tried iodid alone and mercury alone. Either will diminish albumin, but the best results are obtained by the mixed treatment.

I now submit the proposition to the profession and await the result.

GOLF FROM A NEUROLOGICAL VIEWPOINT.

Read at a meeting of the American Neurological Association in New York, May, 1898.

BY IRVING C. ROSSE, M.D.

WASHINGTON, D. C.

Long before the Columbian rediscovery of America our hardy Caledonian ancestry amused themselves by playing the royal and ancient game which has been defined as the putting of little balls into little holes with instruments very ill adapted to the purpose. In those days certain ascetic and lugubrious persons, like the sham-pious reformers of the present, who condemn as sinful anything that makes people feel happy, cried down golf, football and other so-called unprofitable sports, which were prohibited by decree, the legislative blight being a canon of the old Scotch parliament against golf.

Being difficult to extinguish strong instincts, people gave no heed to such prohibitions against the natural and wholesome promptings of the play impulse and manly pastimes of a vigorous race, and today we find a game with a long pedigree taken up and assimilated from Scotland, and so fascinating as to have spread around the English-speaking world.

Instead of dividing mankind, as some mathematicians do, into two classes, namely, those who have read analytical geometry and those who have not, it is now more appropriate to say those who play golf and those who do not, or as an enthusiastic devotee to golf might put it, those who are long drivers and those who are not.

What was yesterday the fad of a few has today become the practice of many sorts and conditions of men, who find in the exhilarating game of golf (which experts prefer to call a *study*) a means of hygiene and sport of inestimable value.

A short time since, in a paper prepared for this Association "On the Conservative Value of the Play Impulse," I endeavored to point out the individual and phylogenic good brought about by the exercise of the manly sports and amusements that brought together men and women of the leisure class at such places as the tennis court, the hunt, the meet, the golf links. Since then the game of St. Andrews in Fifeshire has encircled the earth, like the world-invading Campbells, and the descendants of a race to which piper Findlater belongs take their amusement seriously at sea-side links or on grassy moorlands at a game than which none is a severer test of nerve and none requires more stupid, dogged patience and harder work.

Any golf player familiar with the niblick shot out of sand in front of a bunker cliff will, I am sure, recognize the cool judgment and prompt action required by a successful player who makes a good drive and avoids or extricates himself from awkward hazards, as well as the many advantages entailed thereby in the way of invigorating and healthy employment of the highest bodily activities.

Doubtless from the sportman's point of view and that of the hygienist, the value of golf is quite apparent, but its therapeutic value, not so well established, is practically an untrodden field and in need of an exponent.

In the capacity of physician and neurologist it is impossible to familiarize one's self with the facts of the game in this relation without seeing its many advantages and acknowledging merits beyond all praise.

To the neurologist, who trusts to psychic, mechanical and hygienic influences rather than to drugs for treatment, the theme is replete with magnificent possibilities of prophylaxis and even of therapeutics. We have a royal road to physical exhilaration in a game that can be played all the year round, independent of atmospheric vicissitudes, during all the seven ages of man, by delicate young girls as well as by strong athletes, and even by decrepit old men, whose declining powers do not admit of severe exertion. It combines exercise, pleasure and fresh air without the risk of injury to heart, lungs or nervous system of some other exercises in which there is high blood pressure and arterial tension. To be more specific, there is absolutely no danger attached to the game, and consequently no accidents ensue. Unlike the bicycle, it is doubtful whether such a thing as an accident insurance was ever paid for injury incurred at golf. Nor is the game contraindicated in heart lesions, arterial calcification, albuminuria, old age, childhood and certain hysterical conditions which would be aggravated by such exercise as bicycling, swimming, horseback riding, or by mountain climbing.

To be more explicit, I may say that in all affections marked by slowing of oxidation, or in those consequent upon intoxication by the products of organic disassimilation, the game of golf is to be recommended as the best adjuvant method of bringing about a cure.

The obesity and degeneration of middle age, when the biceps has diminished and one's energy is wanting, may be helped by devotion to golf. The further tendency of the exercise is to eliminate the so-called diatheses and thus do away with gout, lithemia, headache and dyspepsia; while its hygienic and therapeutic consequences are admissible in cardiac and pulmonary affections. Although moderation is advisable in such circumstances, there can be no doubt of the benefit derived in some cases of cough, nervous asthma, and in affections of the bladder and prostate.

But it is pre-eminently in functional nervous disease that our great Anglo-Saxon game is to be recommended, both as prophylactic and curative. No exercise or recreation is better for the mentally overworked, the hysterical, the melancholic; none helps to preserve the concerted action of eye, brain, and muscle known as the psychological moment; none, perhaps, with the exception of swimming, gives one so good an appetite; there is not a more sovereign remedy for dyspepsia, and as to insomnia, such a thing scarcely exists among the devotees of golf.

Improvement in appetite and digestion has come under the notice of nearly every one connected with a golf club. Only two years ago the breezy air of the Newport golf-green caused such an improvement in this respect that the members of the club discharged a French for a negro cook, whose dishes were considered more wholesome and better suited to a golfer's appetite.

In addition to the unconscious vigor of body and

mind imparted by golf, the social amenities arising therefrom are of unquestionable therapeutic value, since the genial influences of the game, by expanding the ideas, tend to promote the good fellowship that comes from diversion and sensuous amusement, and by oiling the wheels of life, so to speak, makes them go on with rattling glee. In these days of excessive drive, competition and over-pressure, when undue waste of vital energy shows itself to the clinician in the way of various neuropathic conditions and decayed nerve elements, the problem of averting or mitigating such mischief comes to us with much seriousness. An obvious help in the solution is the encouragement of all innocent sports and recreations as a compensating factor in the phenomena of life. The condition applicable to the greater number is partly met by the present "boom" in a game that accurately reflects and expresses a great race and falls in with the spirit of our age of haste and subjectivity.

If there be one innocent recreation adapted more than another to all sorts and conditions, but more especially to the gloaming of life, when the mind needs an alternative, that healthful tendency is to be found in the national game of Scotland.

MEDICO-INSURANCE.

Presented to Section on Practice of Medicine at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY S. T. McDERMITH, M.D.
DENVER, COLO.

Briefly as possible I will venture a few suggestions along lines that point to a domain unexplored by this Association, or at least unoccupied by this body. It is a virgin field, inviting the cultivating touch of the medical husbandman; an undeveloped province awaiting conquest.

For fifty years the profession of this country has had vague cognizance of the existence of such an Eldorado, but has never braved the wilderness, the tropics or the desert, to reach it.

The populace of this country had a vague knowledge of the Philippine Islands; that much of our hemp and palm leaf fans and manila wrappers for cigars were imported from there; but not until the echoes of Dewey's guns and the dull thud of a Spanish fleet striking the bottom of Manila bay and starting from its lethargy a civilized world, was any interest manifested in those tropical isles so rich in natural resources.

So I say for years the profession has, in a desultory way, and incidentally, had to do with Medico-Insurance, but no influence has been sufficiently exerted to arouse it to an appreciation of this rich isle in the Medical Pacific; rich in subjects for study and rich in results.

The writer, mindful of the couplet that

"Fools rush in
Where angels fear to tread,"

has no expectation that this shot will electrify a profession, an association, or section, and start it charging to encompass the goal, but he hopes that it may modestly contribute to forces whose captains and commanders yet to be chosen may ring the changes and fire the ordnance, the echoes of which may be heard to the uttermost confines of this Association's domain.

When you stop to consider that the personality and skill of the physician are important factors in commercial transactions involving billions of dollars, as the combined life insurance bodies now do, providing a source of income to the profession, of millions of dollars annually, is it not amazing that this Association, the most important and authoritative organization of medical men on this continent, has given the subject no recognition? Is it not astonishing that the insurance interests have not ere this demanded recognition?

It has ever been taken for granted that a physician, any physician of recognized good standing, was fully competent to prosecute an examination for life insurance.

Prior to the advent of specialties in medicine, it was likewise assumed that the general practitioner, the only kind of practitioner then known, was quite competent to diagnose and treat diseases of the female organs, genito-urinary or skin affections, ophthalmic and aural ailments, equally with fevers and all other systemic derangements.

If any logic will justify specialties in medical practice, it will equally sustain the demand for special study as a requisite to competent work in the field of medico-insurance.

However well equipped a medical man may be for encountering the host of destroyers in the open field of pathology, without self or other training for medico-insurance, he is incapable for estimating the factors which go to make up the rating in a given case. And the lack of familiarity in this operates to render his examinations and report thereon indifferent, or of doubtful value.

The whole scheme of life insurance is based, not on certainties, but on probabilities, yet it is the business of the actuary with the essential aid of the examining staff to eliminate all of chance that it is possible to eliminate, by adding pillars of strength to the structure's foundation, and this consists in the judicious selection of life risks, and the responsibility for such selection rests almost wholly with the medical examiner; and how, without special study fitting him for the work, can an examiner meet that responsibility and render a service consonant with the demands of the service?

To attempt to enumerate, much less discuss the subjects for study which naturally group themselves under the general heading of medico-insurance, would extend this paper to unreasonable limits. A few examples are alone sufficient to suggest the broad field that is open to those who would till it. But I insist that this Association should be the gateway to that field.

First. "Appendicitis as a factor in insurance."

Second. "Consumption from an insurance standpoint."

Third. "Cancer and its relation to insurance."

Fourth. "Syphilis, its bearing on life risks."

These, with hosts of other sub-titles entering into personal or family history, together with the weight of the applicant in relation to height, the occupation, habits, environments, etc., are subjects for chapters and volumes, which should vitally concern any one essaying the important rôle of medical examiner.

The British Medical Association has inaugurated a Section devoted to this special study, the first session having been held last week at the meeting of the

Association in Edinburgh. The Section is there given equal recognition with Medicine, Surgery, Ophthalmology, or any other recognized branch of the profession.

Insurance medicine has therefore, in a sense, been legalized as a specialty by a scientific body which easily stands at the head in the civilized world. It would be appropriate for this Association to early follow the example.

That there is a demand for opportunities to cultivate and develop this important field, and that there is an awakening along these lines, it only need be mentioned that special, independent associations have been formed, as "The Association of Medical Directors," an organization of Medical Directors of old line companies, "The Chicago Association of Medical Examiners," "The Pacific Coast Examiner's Association," and other independent societies, besides the Sections in the Fraternal Congress and the Mutual Life Underwriters' Association, devoted to the subject. I am informed, too, that special courses on insurance have been provided in a few centers of medical tutelage, in the University of Yale and the Vanderbilt University, and perhaps others.

So, since the growing need of a wider dissemination of medico-insurance knowledge is so apparent, I would venture to suggest that its recognition and fostering through the medium of either a separate Section or as a sub-division of the Section on Practice of Medicine would be a move in harmony with progress, in keeping with the needs of the profession, and would comport with the objects and dignity of this, the largest and most august Medical Society in the land.

SURGERY OF THE LUNG.

The Oration in Surgery Delivered at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Col., June 7-10, 1898.

BY J. B. MURPHY, M.D.
CHICAGO, ILL.

(Continued from page 216.)

INFECTIVE LESIONS OF THE LUNG WHICH CONCERN THE SURGEON.

The surgical infective lesions of the lung are abscess, bronchiectasis, gangrene, foreign bodies, cysts (echinococcus and dermoids), tuberculosis and actinomycosis. Abscess of the lung is not as common a pulmonary affection as might be inferred from the number of cases reported as such in the literature. A careful scrutiny shows that a considerable percentage of the cases reported as abscesses are empyema communicating with the bronchus, subdiaphragmatic abscess rupturing into a bronchus, or circumscribed interlobar pleuritis.

Abscess—Etiology.—The most common cause of abscess of the lung is: 1, acute circumscribed inflammation, as pneumonia, followed by necrosis and softening of the lung, 46 per cent.; 2, peribronchitis; 3, septic embolism of the pulmonary artery, or a single branch of the bronchial (pyemic embolism), 3 per cent.;⁴³ 4, rapid tubercular caseation and necrosis, with secondary infection; 5, perforation of the lung by infection from malignant diseases of the esophagus and mediastinum; 6, subphrenic perforations into the lung with retention; 7, foreign bodies in the bronchi 11 per cent. (Tuffier); 8, infections following injuries;

9, suppurative inflammation around calcareous deposits, the latter either a sequence or a cause of the suppuration. From the above it will be seen that the pathology of abscess of the lung is as varied as its etiologic factors. Its clinical course, its treatment and its termination will vary with its etiology; what then concerns us most as surgeons is its diagnosis and treatment.

Symptoms.—The symptoms will vary also with the etiology; take, for example, an abscess following pneumonia. The case runs the ordinary course of a pneumonia; there is nothing special to indicate the probable necrosis and suppuration of the lung during the course of the disease till the time for resolution has presented itself: when the time has arrived for the cessation of fever, cyanosis, delirium and toxic symptoms the sudden change so characteristic of pneumonia does not take place. The fever continues with more marked morning remission and evening elevation. The hectic flush and sweats are more pronounced; the tongue remains dry, coated and cracked; in other words, the symptoms of pus infection have supplanted the symptoms of pneumonia. In some cases there is a sudden expectoration of a large quantity of pus in which may be found lung tissue and various micro-organisms, as pneumo- and staphylococci, bacillus communis coli, etc. The expectoration is most frequently fetid, though not necessarily so. This fact aids materially in making a diagnosis. If the abscess be caused by a septic embolus, by a foreign body, perforation of the esophagus, etc., the history will vary from the above. Where it is produced by the suppuration of a cyst, as a hydatid the characteristics (hooklets) will be present; again, when a dermoid in the chest cavity suppurates and opens through a bronchus there will be found sebaceous material, hair or even teeth in the expectoration. (Ogle-Godlee.)

Physical signs and diagnosis.—The physical signs will vary with the size, location, presence or absence of bronchial communications and etiology; the presence of dullness, the absence of respiratory sound, absence of cavernous breathing, the diminished vocal fremitus, the absence of intercostal movement in respiration, the stationary area of dullness, lead to the belief that there is an accumulation of fluid; a differential diagnosis must then be made between cysts, pleuritic effusion, gangrene, abscess, and consolidation. Inspection shows a marked loss of respiratory movement and occasionally signs of edema where the abscess is situated close to the chest wall. If it be deep in the lung the respiratory movements may not be interfered with. Percussion where the abscess does not communicate with a bronchus reveals a circumscribed dullness. If the abscess communicates with a bronchus we may get a cracked-pot sound, or the dullness may be the same as if non-communicative if the cavity is kept constantly full of pus. Great care should be taken in making comparison between the deep and superficial percussion notes to determine if lung tissue intervenes between the abscess and the chest wall; the area of deep and superficial dullness should be carefully outlined on the chest surface.

In auscultation the sounds will vary, depending upon the presence or absence of bronchial communication. There may be a superficial respiratory murmur with a deep abscess. The vocal fremitus is diminished. If the abscess be large, distant bronchial breathing can often be detected. When bronchial

⁴³ Porter: Jour. Amer. Med. Association, March 9, 1891.

communications exist we have the amphoric breathing, often the distinct metallic tinkle, the whisper sounds and the gurgling. In pulmonary abscess and bronchiectatic cavities the stethoscopic examination is liable to be misleading as to their location, they often appear to be situated farther from the hilum than they are in reality. In my experience this was not true, as the percussion and auscultation revealed the location when the cavity was situated in the anterior portion of the lung.

Exploratory puncture has been considered the crucial test, although authors differ widely as to its value and significance as a negative manifestation. E. Bull considered it of only moderate value; still he insists that it should always be used where drainage is indicated. He attributes its deficiencies, 1, to failure in proper location of abscess by other physical signs and therefore not reached by needle; 2, to a plugging of the needle before the cavity is reached, and 3, to abscess contents being too viscid to pass through the needle. Tuffier says exploratory puncture is permissible but often deceptive, and when negative the puncture is to be made many times. In his cases he made from two to twelve punctures in each case and found with this large number of efforts he failed to locate the cavity in 17 per cent. of the cases of gangrene, 17 per cent. of the abscesses and 33 per cent. of the bronchiectases. He further states that puncture is harmless when done at the time of operation, but at other times may be dangerous; it is deceptive, as it does not show the multiplicity of the lesions. He found in twenty-eight cases that the primary exploratory puncture produced positive results in sixteen, multiple punctures added seven positive results to the number, and in five the result was negative. Foul gas in the syringe is just as positive, from a diagnostic standpoint, as pus. Bushnell favors repeated punctures for localization.

The dangers of exploratory puncture are: 1. Hemorrhage. In recalling our anatomy we are reminded that a blood vessel accompanies each of the bronchi; these are likely to be punctured in exploration, give blood in the hypodermic, and may be followed by fatal hemorrhage; a case is reported by Fraentzel. In two of my cases of bronchiectasis there was considerable blood expectorated after puncture, but not sufficient to cause alarm. 2. Infection of pleura. The literature supplies a number of cases in which the pleura became infected following exploratory puncture, either from the escape of pus through the puncture canal, or from an advancement of the process along the canal into the pleura subsequently, producing an infective pleuritis. 3. Gangrene. A gangrene along the line of puncture involving the external chest wall has followed exploratory puncture, therefore exploratory puncture is not as harmless even in pleuritic adhesions as might be believed. 4. Pneumothorax. This has proved to be a serious complication following exploratory puncture only when accompanied by infection. I am convinced that exploratory puncture in the surgery of the chest, for diagnostic purposes, will not become a common procedure except for localization at time of operation.

Location of the abscess.—The abscess may be situated in any portion of the lung. Tuffier found it in the lower lobe in 80 per cent. of the cases and most frequently in the posterior portion of that lobe. With the aid of the radiograph we are able to determine if the abscess be close to the anterior or poste-

rior wall of the chest, as can be seen from radiographs of Miss K.

Treatment.—After the diagnosis has been determined, should the treatment be palliative (therapeutic, pneumothorax, puncture with trocar or aspiration) or surgical (resection of chest wall with compression of lung over abscess, incision with drainage)? That will depend somewhat on the etiology and location of the abscess, but more particularly upon its size. Should there be an absence of adhesion and the lung collapse when the pleura is opened, and if the abscess communicates with a bronchus, it would seem from a theoretical standpoint that it should drain and close. Thoracotomy in this manner is so easily performed that it appears to me applicable in the class of cases in which pneumotomy is most dangerous, *i. e.*, where there is an absence of adhesions. It allows of, *a*, drainage through the bronchus; *b*, contraction of the cicatricial abscess wall; *c*, peripneumonic compression from the air in the pleural cavity. All of these should favor the repair of the abscess. We know from the results following operations for pyo- and hydrothorax that the lung after a long period of compression, re-expands and functionates; this point is most forcibly illustrated by the cases of Delagénier. If pleuritic adhesions exist there can not be a general collapse of the lung; it would only be partial.

Puncture and aspiration as treatment for abscess of the lung has rapidly fallen into disuse. William Koch favored this procedure, as he feared pneumotomy. The treatment of suppurating cavities by means of aspiration in most positions in the body has been very unsatisfactory, and abscess of the lung is no exception to the general rule. The trocar and permanent canula have been advised and used in cases with adhesions, and particularly advocated when adhesions did not exist; the canula was intended to conduct the septic material across the pleural cavity to the opening in the chest wall. Dr. E. Fletcher Ingals⁴⁴ reports three cases treated by aspiration alone; all recovered. He states the diagnosis of abscess was not confirmed by microscopic examination and might have been circumscribed or interlobar pleurisy. Dr. McArthur, in discussing Dr. Ingals' paper, advocated operation with packing of pleura with gauze to protect the pleura when adhesions were absent. T. Anderson⁴⁵ successfully operated a case by first introducing a trocar, waiting two days and then dilating with artery forceps; there was no hemorrhage. Cummins⁴⁶ did a similar operation with recovery.

It would seem far preferable in these cases to make a large free opening in the chest by resection of the sixth, seventh and eighth ribs, pack gauze around the infected area, open the lung cavity and freely drain the costo-diaphragmatic cul-de-sac, as advised by Delagénier for empyema.

The canula and trocar have been used with indifferent success in the treatment of pulmonary abscesses; while its inefficiency has not been so pronounced in abscess as in gangrene, the records show that it is far from satisfactory and not free from danger; in many cases secondary thoracotomy and pneumotomy had to be performed. A case forcibly illustrating this point is reported by J. Eustace Webb,⁴⁷ where an apparently perfect drainage through the

⁴⁴ Jour. Am. Med. Association, Vol. xxviii, 1896, p. 397.

⁴⁵ Am. Prac. and News, Louisville, 1890, N. S. X., 10-12.

⁴⁶ British Medical Jour., 1889, Vol. i, p. 209.

canula ceased after six weeks; a few weeks later a pleurotomy had to be performed on the anterior side; patient recovered. H. Havelock Davies reports a successful case with the canula and trocar treatment.⁴⁸

Bull, in 1884, urged that all abscesses should have artificial fistulae established; that all cavities should be drained to prevent secondary results. He realized the difficulty of estimating the size of the cavity and differentiating between one large cavity and multiple closely allied small ones. He considered that tuberculosis was a positive contraindication to the establishment of drainage.

By an external physical examination we are unable in the great majority of cases to determine the presence or absence of adhesions. Occasionally a friction sound will be heard, which will indicate that there are no adhesions at that point. I have demonstrated that the absence of adhesions can be positively diagnosed. By introducing an exploring syringe trocar through the skin into the intercostal muscles; the stilette is then withdrawn and the trocar is connected with a filter bottle to which a bag of nitrogen gas or sterile air is attached; a slight pressure is placed on the reservoir and the trocar is pushed forward until the parietal pleura is penetrated; if adhesions do not exist the gas will suddenly commence to flow and the lung will collapse. On the other hand, if the lung be adherent, the trocar will traverse the parietal and visceral pleurae and penetrate the lung and the gas will not flow. To illustrate:

Case 1.—Mr. K., clerk, age 24, Cook County Infirmary, admitted to hospital April 30. Suffering with tuberculosis of the right apex; physical signs extending down to the margin of the third rib in front; tubercle bacilli present. He was placed on the table and a puncture made with the trocar, as described above; when the parietal pleura was punctured the gas was seen to suddenly pass through the filter solution and soon the physical signs of pneumothorax presented themselves; 120 cubic inches were injected, proving absence of adhesions. The history of this case will be given in full in connection with the treatment of tuberculosis by defunctionalization.

Case 2.—E. L., male, age 34, Cook County Infirmary. Phthisis in second stage, with cavity in right upper lobe; the method was the same as was used in the preceding case; after the insertion of the trocar there was no escape of gas until the lung was deeply penetrated, then it passed freely and was detected in the upper air passages; there was no collapse of the lung; no inconvenience was produced by the injection, showing that adhesions existed.

Bull considered it was not necessary to a good result in opening abscesses that adhesions should be present; this is also shown by the case of Kroenlein. One of the indications given by him for success, was that the cavity must be near the surface, and if adhesions were not present a trocar should be used to conduct the pus out of the pleural cavity. He advised the use of caustics to produce adhesions. This, however, had been advised previously by Krimer in 1830. Péan, in 1861, suggested suture of the visceral and parietal pleurae for the production of adhesions before opening the abscess cavity. Barry and Graux also advised this method. Godlee suggested puncture for the production of adhesions. Mosley favored salicylic acid. Quinke urged zinc chlorid for the same purpose; Krause, a tampon. Quinke made fifteen experiments for the establishment of adhesions by suture; his results showed the method a failure.⁴⁹ Tuffier found adhesions present in 87 per cent. of the septic cases.

Tuffier,⁵⁰ in his most excellent paper, considers that the dangers are great where adhesions do not exist and that opinion was based on his experience in eight cases in which complete pneumothorax occurred during the operation; in two death was immediate; one died a few hours after the operation; two recovered (suppurating foci not opened); one recovered (focus opened four months later), and one with immediate opening of focus. The first three of these results appear to be attributable rather to the character of the opening than to the presence of a pneumothorax. From a perusal of the most recent cases reported and from my experiments I feel convinced that adhesions are not necessary to success, and furthermore that their absence has advantages, as then the entire hand may be inserted into the chest for the palpation of the lung and location of abscesses; further, I am convinced that abscesses without adhesions, and with bronchial communications, should not be treated by incision and drainage through the chest wall, but by producing collapse of the lung by injecting nitrogen gas or a liquid into the pleural cavity, thus compressing the lung and allowing the connective tissue in the wall of the abscess to contract and obliterate the cavity with the aid of the bronchial drain.

Operation.—In abscesses of the lung the earlier the operation the better the prognosis (Sonnenberg). The incision in the chest wall should be the U or H shape which admits of an extensive resection and thorough exploration of the field in which the abscess is located. The ribs should be resected subperiosteally, if possible without opening the pleura. After the chest has been opened and adhesions found present, the location of the abscess must be determined; this may be accomplished with the exploring needle, with the scalpel, or, better still, by careful digital palpation. The lung may be pushed away from its parietal adhesions and a digital palpation made in every direction until the position of the abscess is determined, then the exploring needle may be used to confirm the diagnosis. The scalpel should be used to incise the lung and abscess wall. E. W. Andrews favors the scalpel, and successfully incised an abscess four inches below the surface of the lung and removed thirty-five grammes of calcareous material from the cavity. The hemorrhage is unpleasant but rarely dangerous, three serious cases having been reported, one by Quinke, and two fatalities, one each by Fabricant and Andrews. In the latter case no autopsy was permitted. The patient had several severe hemorrhages preceding the operation; it is presumable that the fatal hemorrhage was from the same source. The hemorrhage following the incision can be controlled by compression, or better, by accurate catgut suture. I found the latter more satisfactory in my experimental work. The scalpel is preferable to the cautery; it produces a clean incision; it allows of inspection of the tissues divided: it permits a view of the cavity when opened and a suture of the lung tissue for hemostasis if necessary; the cautery may be used on the incised surface to still the bleeding. There is, however, with incision some danger from air embolus of the pulmonary vein, as the blood here may have a minus or a very feeble plus pressure, and in deep inspiration the air is aspirated into the vein. Quinke reported a fatal case of this character. Reclus favors the Paquelin cautery for opening the abscess. If

⁵⁰ *Inter. Med. Cong.*, Moscow, 1897.

the lung recedes after the division of the pleura the opening should be rapidly enlarged and the hand or cyst forceps inserted to draw the lung out. It can be retained here by sutures to the parietal wall and packed around with iodoform gauze. The lung in this position admits of accurate palpation and if the tampons are properly placed there should be little risk in the immediate opening of the abscess. A large drain of soft pure rubber should be inserted and secured by suture to the lung and chest wall; or, better still, rolled gutta percha paper or gauze drain may be used. The rubber drain has been charged with being the immediate cause of hemorrhage from pressure necrosis of the vessel wall. (Walsham and Sutherland.)

The irrigation of pulmonary cavities is rapidly going into disuse: it produces unpleasant symptoms and in one case caused a fatal result—laryngo bronchitis—boric acid and thymol having been used. H. W. Austin⁵¹ reports a case in which irrigation with bichlorid was used without producing unpleasant symptoms, although the patient almost drowned from rupture of the abscess into the bronchus during operation. Case recovered.

Experiment 1.—Nov. 1, 1897; black dog, weight about 30 lbs.; right side of chest was shaved and rendered aseptic by scrubbing with soap, ether, alcohol and bichlorid 1:1000; ether anesthesia; usual antiseptic precautions with instruments, ligatures, towels, lap sheets, hands, etc.; an incision 3 inches long, over and parallel to the second rib was made; resected three inches of the latter; the pleura was incised for two inches; immediate collapse of the lung was observed: the vibrations of the mediastinal septum were watched and it was noted that with each inspiration it vibrated farther to the left and with each expiration farther to the right; it became thinner and thinner until it was a mere film and looked as if it would rupture; the attenuation took place anterior to the mediastinal contents; the dog became cyanotic and finally ceased breathing; the chest walls were then compressed and the opening in the right side closed by the palm of the hand; when the chest expanded the dog began to breathe regularly and rapidly; his cyanosis quickly disappeared; when the hand was removed respiration would rapidly cease, when replaced it would go on as before; it appeared to make no difference whether the aperture were closed at the end of inspiration or expiration. The upper lobe was drawn out through the opening with the forceps; the apex was split with the scissors down $1\frac{1}{2}$ inches; the incision was closed by accurate continuous catgut suture; the lung was dropped back into the chest and the opening closed with a deep suture of muscle and fascia with catgut and a subcutaneous buried suture of the same material; the dog was not sick after the operation; as he absconded on the twelfth day I was unable to obtain the specimen, with which I wished to show the histology of repair of incision. The literature furnishes us many reports of repaired punctured and bullet wounds of the lung. The restoration is so perfect that it is often difficult or even impossible to locate the track of the missile from the pathologic evidence. I therefore did not repeat this simple experiment.

Prognosis.—Reclus reported 23 pneumotomies for abscess, with 20 recoveries and 3 deaths. J. Schwalbe* says that, of 50 per cent of the cases operated for acute and chronic gangrenous abscess recovered and 40 per cent died. In chronic bronchiectatic and simple abscess only 16 per cent recovered, 41 per cent died. Of 43 cases collected by Tuffier there were 10 failures; in 7 per cent of these the failure was due to inability to locate the abscess, from an inexact diagnosis or from the absence of adhesions. Fabricant reports 17 abscesses following pneumonia all operated, with 14 recoveries; 7 following infection, with five recoveries; 3 suppurating hydatids, all recovered; 2 gunshot wounds, both recovered: in all, 29 cases, with 24 recoveries. J. Blake White per-

formed pneumotomy twice on the same patient at an interval of three months with success. Ramsay† reports four cases of pneumotomy. The ultimate results, when the abscess has been opened and drained, are favorable, particularly in the acute abscesses following pneumonia: the subacute or chronic heal slowly with prolonged or permanent fistulae. The earlier the operation the more certain and rapid the healing, as the wall is thinner, the cavity usually small and the reparative process more rapid. I have collected 71 cases of abscess of the lung; of these 49 completely recovered; 5 recovered with fistulae; 16 died, 1 from the operation, 10 from undetermined causes, 3 from exhaustion, 1 from hemoptysis, 1 case was lost sight of.

Lung Abscesses from 1878 to 1897, years in rotation.

Case 1, 1878. Radsch, Centralblatt f. Chir., 1878, No. 44, p. 750. Male, aged 44 years. Two large abscesses in region of right mamma. Empyema necessitatis, with communication with right bronchus; located in region of right mamma; incision and escape of one liter of pus; irrigation with carbolic acid, followed by rise of temperature. In next few hours there was improvement. Death in 29 hours. Necropsy: Large abscess cavity in lower lobe and fresh pleuritis on opposite side.

Case 2, 1879. Austin, Rep. of Super. Surg.-Gen. Marine-Hosp. Service, Vol. 17, 1879, p. 246. Male, aged 21 years. Empyema and abscess of lung, duration 3 months. Had a cough. Located in left side; abscess in upper lobe of left lung; abscess probably communicated with pleural cavity. Aspirated several times about 1 month before operation; aspiration showed a clear fluid at time of operation; puncture almost pus. Incision $1\frac{1}{2}$ inches long in axillary line between 9th and 10th ribs; rubber drainage tube inserted, 5 quarts of offensive pus escaped at once; 3000 c.c., 1-4000 HgCl. solution irrigated. Recovery, with persistent fistula.

Case 3, 1879. Sedgwick, Lancet, March 29, 1879, p. 441. Abscess of lung. Typhus. Puncture twice at short intervals.

Case 4, 1882. Fime, Norsk Mag. for Hæger, 1882, No. 22, in Runeberg obs. 4. Female, aged 4 years. Abscess of lung. Duration 7 weeks. Acute lobar pneumonia upper left lobe. Location, apex of left lobe in front. Incision in 2d or 3d intercostal space; pneumotomy; Pus had mixed with air; drainage. Slow recovery.

Case 5, 1882. Lancet, 1882, Vol. 1, p. 601, Payne. Male, 23 years. Abscess that had been diagnosed as purulent pleurisy. Acute inflammatory affection of lung (pleurisy). Located at base; adhesions. Puncture, axillary line; positive result. Incision, pleurotomy (venous hemorrhage); drainage. Temporary improvement; patient died seven days after. Necropsy: No pleurisy; abscess of lung; report not very precise.

Case 6, 1882. Quiss, Wiener Med. Woch., No. 3, Vol. 3, 1882, p. 364. Male, middle aged. Abscess. Pneumonia; fluctuation on chest wall. Incision 1 cm. long in seventh interspace, large quantity of pus removed two hours after operation; great bleeding; gradual improvement. Dismissed in seven weeks cured.

Case 7, 1884. Rohden, Deut. Med. Woch., 1884, Vol. 14. Female, 20 years. Empyema and abscess of lung; duration two months. Left-sided pneumonia, on lower left side. Puncture at angle of sixth and eighth ribs, emptying 100 c.c. of fetid pus. Thoracotomy on August 8; drainage and irrigation with salicylic acid sol.; fever diminishes and improvement sets in; on August 30 drain is removed, temperature now rises and patient becomes worse; the wound reopened, drain and finger introduced; abscess of lung is thus opened and pus escapes; continuous irrigation. Improvement; after several months the fistula is healed.

Case 8, 1884. Pridgen, Teale, Lancet, 1884, Vol. 2, p. 6. Male, 54 years. Pulmonary abscess cavity. Pleuro-pneumonia one month before. Location at base of right lung posteriorly; pleural adhesions. First puncture, serous liquid; second puncture, pus; two days after cavity punctured with trocar, fetid pus. Incision at right of puncture; pleural cavity contains no liquid; puncture of adherent lung yields pus; opening enlarged with finger, escape of two pints of pus; drainage, carbolic irrigation. Recovery; drain removed five months after. Patient seen three years after; some retraction of thorax and feeble respiratory excursion on right side; later patient had two operations with death.

Case 9, 1884. Waugh, quoted by Tabacat. Male, 53 years. Abscess of lung; acute pneumonia of left lung. Resection in ninth intercostal space; profuse hemorrhage, checked by tamponade. Good and complete recovery.

Case 10, 1885. Broadlett, Med. Jour., May 31, 1884. Large cavity in lower left lobe, which was opened, followed by slight improvement. Cavity opened. Death.

Case 11, 1885. Andrews, Jour. of Am. Med. Assn., 1885, Vol. 5, p. 261-265. Male, 28 years. Abscess of lung. Located left side posteriorly. Signs of cavity. Puncture between fourth and fifth ribs, no result; second puncture in anterior chest wall, finds pus. Incision on needle, no rib resection; large amount of fetid pus escaped; irrigated with carbolic solution. Recovery rapid and complete.

Case 12, 1885. Korobeln, 1885, quoted by Fabricant. Female, 11 years. Abscess of lung and empyema. Located in left lung. Positive puncture. Resection after eight days' drainage; after seven months wound made larger. Recovery.

Case 13, 1886. Bouilly, 1886, quoted by Fabricant. Male, 46 years. Cavity in upper right lung. Echinococcus removed 10 years ago by expectoration. Located in upper right lung; pleural adhesions. Resection of 6.7 cm. from third and fourth ribs; pneumo-cautery used. Recovery; left on eighteenth day.

Case 14, 1887. Hassen, Mang. Dissect, Kiel, 1886, et Berlin Woch., 1887, Obs. du Quinke, p. 138. Female. Old pulmonary abscess or bronchiectasis. Duration twelve years. Pulmonary affection of undetermined nature; base of left lung. Signs of cavity; no adhesions. Exploratory puncture axillary line, negative; five injections of one-fourth or one-half tinct. of iodine; second puncture at same point yields a few drops of very fetid pus. Died three weeks after of purulent pleurisy.

Case 15, 1886. Rockett, 1886, Wid. Abscess. Resection. Recovery. Case 16, 1886. Wiener Med. Presse, 1886, p. 1235. Male. Chronic abscess; base of right lung; pleural adhesions. Incision in sixth intercostal space; pneumotomy and drainage. Death eight days after, abscess communicating with abscess of liver.

⁵¹ Marine Hosp. Rep., Washington, 1889, p. 246.

* Cent. f. Chir., vi, p. 171.

† Ann. Surgery, St. Louis, 1890, xi, p. 43.

Case 17, 1887. Quinke, loc. cit., p. 20 and 21. Obs. 2 at Berlin Klin. Woch., 1887, p. 337, et in hasse loc. cit. Male, 26 years. Chronic abscess; pneumonia two years before, base of left lung posteriorly. No signs of cavity; no adhesions. Incision: zinc cl. 2 paste, in ninth intercostal space, repeated several times; resection of 4 cm. of ninth rib; puncture incision with thermo-cautery; treatment lasted three months. Pus is voided by wound for three weeks after operation; recovery with fistula. Saw case twelve years after; has a fistula which secretes a little.

Case 18, 1887. Runeberg, Deut. Archiv, 3, Klin. Med., 1887, p. 91. Male, 33 years. Acute abscess; five weeks; chronic pneumonia; base of right lung beneath spine of scapula. No signs of cavity; adhesions; exploratory puncture. Resection of sixth rib on axillary line; incision of a superficial abscess; irrigation with carbolic and drainage. Recovery in two and a half months.

Case 19, 1887. Thiriar, Bull. Acad. de Med. de Belgique, 1887, No. 10. Male, 22 years. Pulmonary abscess, hemoptysis; base of left lung posteriorly; adhesions: two negative punctures. Resection of fifth, sixth and eighth ribs; large resection; horizontal incision extending from 15 cm. of axillary line to angle of vertebral column along eighth rib; a vertical incision 5 cm. from vertebral column; opening of cavity with thermo-cautery. Recovery.

Case 20, 1887. Zielavitz, Deut. Med. Woch., 187, Vol. 13, p. 239. Male, 15 years. Empyema; abscess of lung found at operation for empyema. Morbid pneumonia; three months later an empyema was found; lower left lobe. Resection of sixth and seventh ribs, exudation cleaned out; irrigation; abscess cavity opened along fistulous tract through empyema, incision; opening tamponed with iodoform gauze; empyema cavity tamponed. Patient cured in eight weeks.

Case 27, 1887. Zielavitz, Deut. Med. Woch., 1887, Vol. 13, p. 239. Male, 15 years. Empyema with abscess of lung; abscess of lung healed was found at operation for empyema; a few weeks before empyema was opened. Seventh rib resected at a second operation for the empyema; cavity was cleaned out; healed abscess cavity was discovered. Recovery complete in six weeks.

Case 21, 1888. H. N. Davis, London Lancet., Vol. 2, 1888, p. 419. Male, 21 years. Abscess of lung. Duration from beginning of sickness, about three years. Subacute pneumonia of left side, a year later consolidation of right lung; right side. Signs of cavity. Positive puncture in fifth interspace; anterior axillary line. Incision, upper border of sixth rib; trocar and canula introduced, a quantity of fetid pus removed; cavity washed out twice daily with carbolic col. for three weeks. Recovery; one and one-half months after operation cavity was closed; patient completely recovered and well and at work five months after.

Case 22, 1888. Godley, Brit. Med. Jour., 1888, Vol. 2, p. 880. Abscess; no adhesions. Suture of the two pleurae, pneumotomy. Death three days after from abscess of other lung.

Case 23, 1888. Quinke, loc. cit., pp. 6 and 7, Tab. 1 a, Obs. 5. Male 32 years. Acute abscess. Duration, four weeks. A typical pneumonia ten weeks before; base of right lung posteriorly. No signs of cavity; no adhesions. Paste of zinc cl. 2, in eighth intercostal space; resection of 5 cm. in eighth and ninth ribs; new application of zinc cl. 2 paste nineteen days after exploratory puncture; abscess opened with thermo-cautery, 600 c.cm. of pus removed; treatment had lasted five weeks. Complete recovery in four months.

Case 24, 1889. Cummins, A., British Med. Jour., 1889, Vol. 1, p. 269. Female, 32 years. Abscess of lung; hemoptysis. Duration, six months. There was dulness of clavicular and infra-clavicular regions of left lung; increased vocal fremitus; fluctuation between eighth and ninth ribs on axillary line. Oblique incision, two inches in length, over eighth and ninth ribs, a dram of pus evacuated by means of probe; an opening was found between ribs, this was dilated by forceps and fingers; 3-4 oz. of fetid pus escaped; air passed in and out of cavity with respiration and expiration; pus discharged freely, lost after expectoration diminished; finger inserted every two or three days. Recovery. Patient began to improve and left hospital; re-admitted a few months later and died.

Case 25, 1889. Delpratt, Brit. Med. Jour., Vol. 1, p. 470. Male, 33 years. Abscess of lung. Calculus, pyelo-nephritis; base of left lung; adhesions. Pneumotomy without costal resection; drainage. Drainage tube removed at the end of three months; recovery in six months.

Case 26, 1889. Mosetig Moorhoff, Wiener Med. Presse, 1889, p. 1. Male, 22 years. Abscess following a traumatic fistula. Duration three years. Cause gunshot wound of chest, base of left lung; adhesions. Incision; three months before operation had resected fourth and fifth ribs; diagnosis, an empyema; pneumotomy enabled the operator to remove three fragments of ribs located in the parenchyma. In seven days wound was nearly healed, then Jacksonian epilepsy appeared which proved fatal three weeks after the operation.

Case 27, 1889. Selby, Brit. Med. Jour., Vol. 2, p. 766. Male, 26 years. Pulmonary abscess; axillary line right side at level of fifth rib; no signs of cavity at time of operation; adhesions. Two negative exploratory punctures; third puncture below preceding strikes pus. Resection of one and one-half inches of fifth rib; no pus in pleural cavity, lung hard and congested; abscess was not incised. Fetid expectoration, signs of cavity at base of right lung; recovery.

Case 28, 1889. Jonq, Reder, Tyds. 13, 1889, in Quinke Wilt aus groezgeh, 1895, 1 obs., pp. 6 and 7. Male, 33 years. Acute abscess, lasting several days; pneumonia on fifteenth day; base of left lung. Signs of cavity; pleural adhesions. Exploratory puncture; positive aspiration, lavage injections of iodine; abscess 5 cm. below surface. Recovery.

Case 29, 1890. Herbert Hawkins, Lancet, 1890, Vol. 2, p. 1330. Male, 14 years. Abscess, expectoration fetid; duration three weeks; pneumonia; left axillary region. Signs of cavity; adhesions; there was a consecutive purulent pleurisy. Positive puncture, pus at depth of 5 or 6 cm. Incision without costal resection; adhesions; pneumotomy; drainage. Recovery, but two days after patient had purulent pleurisy; empyema. Recovery in seven months.

Case 30, 1890. Hoffman, Deut. Med. Woch., 1890, p. 1156. Male, 21 years. Fetid metastatic abscess; duration, several weeks; otitis media and pyemia; base of right lung posteriorly. No signs of cavity; adhesions. Positive exploratory puncture. Costal resection; pneumotomy; drainage. Recovery in seven months.

Case 31, 1890. Liedard, Lancet, 1890, Vol. 1, p. 964. Pulmonary abscess; two and one-half months; pulmonary affections undetermined; left base axillary line. Signs of cavity; adhesions. Exploratory puncture in fifth intercostal space; positive. Incision at level of puncture; resection of sixth rib, flow of pus; dilatation of wound cavity covered with calcareous masses; irrigation with boric acid produces coughing spells. Died five days after from hemoptysis. Necropsy: cavity size of goose egg, no bronchial communication, recent tuberculosis.

Case 32, 1890. Ramsay, Obs. 3, Annals of Surg., 1890, Vol. 6, p. 31. Female 17 years. Abscess. Duration, one month: Measles and pneumonia one month before; to left. Signs of cavity. Resection of third, fourth and fifth ribs, opening of cavity with thermo-cautery, tamponing. Septicemia in two months; death. Necropsy: Ramsay says there were multiple abscesses.

Case 33, 1890. Ramsay, Obs. 4, Annals of Surg., 1890, Vol. 6, p. 34. Abscess; few months duration; typhoid fever; inferior lobe of right lung. Resection of third, fourth and fifth ribs under median line; pneumotomy with thermo-cautery, little pus escaped, tamponing. Perfect recovery; patient has been able to resume work.

Case 34, 1891. Green, Lancet, 1891, Vol. 1, p. 193. Male, 6 years. Acute abscess; eight days' duration; pneumonia of five weeks' standing; base of left lung. Puncture in fifth intercostal space in axillary line. Incision: pneumotomy on trocar, drainage. Recovery in twelve days.

Case 35, 1891. Huber, Med. News, 1891, Vol. 30, p. 455. Male, 4 years. Acute abscess; six weeks' duration; pneumonia; left summit forward. No signs of cavity; adhesions. Incisions in third intercostal space without costal resection; exploratory puncture confirmative, dilatation of puncture, drainage. Recovery in eight months.

Case 36, 1891. Indianina, Med. Gazette, 1891, Calcutta in Morillon, These Paris, 1897, p. 5, des Tableaux. Male, 35 years. Abscess of lung opened and fistula; fistula going from below up back toward axilla; four months' duration. Located at base of right lung posteriorly; adhesions. Resection of eleventh rib posteriorly; hemorrhage from intercostal artery, three ounces of fetid pus; irrigation with bichlorid of Hg. Recovery with retraction of thoracic wall.

Case 37, 1891. Terriet, Soc. de Chirurgie, 1891, p. 741; Morillon, Paris, 1897, p. 62. Abscess of lung, secondary to liver abscess that had opened in the bronchi; one year's duration; liver abscess dysenteric; located at base of right lung posteriorly. Signs of cavity; adhesions. Puncture behind in axillary line posteriorly, in eighth interspace; escape of pus. Resection of eighth rib; drainage of abscess; improvement, but accidents of retention cause symptoms of gangrene thirteen and a half months afterward; new resection of eighth rib; incision of lung; this incision leads into a dilated bronchus, curturement of this bronchial dilatation. Complete recovery; patient seen two years after recovery, he is a navy surgeon and can resume his work.

Case 38, 1892. Andrews, Chicago Med. Rev., 1892, Vol. 3, p. 537. Male. Abscess of lung, several years' duration; recurrent pneumonia; cavity of middle lobe; pleural adhesions. First puncture negative, second puncture under chloroform entered cavity at depth of 7 to 8 cm. Incision, trocar inserted in the sixth interspace; pneumotomy; amelioration four months later because of retention; thorocoplasty was made; resection of third, fourth, fifth and sixth ribs in the axillary line opening of a large cavity containing calcareous debris. Recovery with fistula. Death four and one-half years later from acute broncho-pneumonia.

Case 39, 1892. Ricard in Record Gazdeshop of 1892, Maus et Soc. Chir., 1895, p. 689. Male, aged 36 years. Suppurative interlobular pleurisy of left lobe or abscess of lung. Several months; pleuro-pneumonia; traumatic of three months standing; right axillary region; no signs of cavity; adhesions; eleven negative and one positive puncture. Resection of fourth rib on axillary line of seventh and eighth ribs on a level of last puncture; exploratory puncture; opening of cavity with thermo-cautery; cavity was 2½ cm. below surface tamponing. Rapid improvement; recovery without fistula in thirty-four days.

Case 40, 1893. Fairchild, Chicago Clin. Rev. Vol. 9; No. 93 in Wein, klin. Woch., 1893, p. 633. Male, 55 years. Abscess of lung. Pneumonia. Location, base. No signs of cavity; adhesion. Repeated negative punctures; at last a positive puncture in fifth intercostal space. Incision in fifth intercostal space on trocar section of 2 cm. of fifth rib; pneumotomy; abscess containing eleven ounces of pus; drainage; irrigation; no coughing spells. Uneventful recovery in one year.

Case 41, 1893. Huber, Arch. de Balneotherapie, Vol. 10, 1893, p. 1006. Age, 13½ months. Acute abscess. Acute lobar pneumonia. Located at base of left lung. No signs of cavity; adhesions. Two positive exploratory punctures in third intercostal space. Incision upon a trocar as psoas; pleuro-pneumotomy; one and one-half ounces of pus; drainage; abscess communicates with bronchus. Rapid recovery.

Case 42, E. F. Ingals, Jour. Am. Med. Assn., Vol. 27, p. 397. Female, aged 40 years. Abscess of lung. Liver abscess. Located in lower outer cover of right mammary region. Positive puncture; fistula left along needle. Five months after first seeing of patient portions of two ribs resected; lung tissue penetrated and abscess cavity opened; cavity communicated with liver abscess and bronchial tubes; drainage tube. Failed after operation; died in three weeks.

Case 43, E. F. Ingals, Jour. Am. Med. Assn., Vol. 27, p. 397. Male, aged 36 years. Pneumonia. No positive signs of a cavity. Punctured between seventh and eighth ribs near angle; positive; drew off offensive pus; another positive puncture six days after the first; third puncture negative. Recovery.

Case 44, 1893. Monson, A., Lancet, Vol. 1, 1893, p. 1196. Female, aged 32 years. Thrombosis of lung or mediastinal abscess discharging through lung. Duration, five months. Sickness dated from child-birth, about five months before; slight cough before that. Location, right posterior apex. Signs of cavity. Incision in right interscapular region; after piercing third right intercostal space, near angle of ribs, small quantity of pus. Patient died twenty days after operation. Necropsy.

Case 45, 1893. Tizebicky, Wien. klin. Woch., 1893, No. 2, 1722. Female, aged 42 years. Pyemia abscess, duration fifteen days. Peripneumonia infection of two months' standing. Puncture, base of right lung posteriorly. No pleural adhesions. Punctured 500 c.c. of pus. Resection of seventh rib three days after incision; pneumothorax. Death ten hours after. Autopsy: No pleural adhesions; serous pleurisy in stage of resolution; operation in extremis.

Case 46, Chaston by Littlewood, Brit. Med. Jour., 1894, Vol. 1, p. 69. Aged 12 years. Two small pulmonary abscesses. Resection of two ribs; pneumotomy. Recovery.

Case 47, 1894. Delageniere, Arch. Provencales de Chirurgie, 1894, Janvier. Female, aged 37 years. Lung abscess; pneumonia; pleural adhesions. Pneumotomy after resection of sixth, seventh and eighth ribs. Recovery; maintained no fistula.

Case 48, 1894. Kasanli, in Fabricant Chir. Viesnik, 1894, p. 763. Obs. 29. Male, aged 36 years. Abscess of lung; duration, eighteen months. Gunshot wound of chest eighteen months before; base of left lung; adhesions. Incision at time of accident; incision of second and third ribs; persistent fistula; accidents of retention and of septicemia necessitating, eighteen months after, a pneumotomy; eighth rib resected; opening of an abscess. Recovery but still had a fistula forty days after.

Case 49, 1894. Neuber, Mittheil. d. Vereins Schleswig-Holstein Aerzte, 1894, p. 55, in Quinke loc. cit., Tab. IIa, pp. 20 and 21. Male, aged 45 years. Chronic abscess of eight months' duration. Calcareous concretions in bronchi; base of right lobe posteriorly. Signs of cavity; no adhesions. Resection of eighth, ninth and tenth ribs; 18 cm.; pneumotomy six days after; 500 grains of pus and calcareous concretions. Recovery with persistent fistula; patient is alive four and one-third years after; general good health; however, there persists a fistula and a cavity the size of a fist secreting a mucous liquid; bronchi open in this cavity.

Case 50, 1891. Rochester Med. News, 1891, in Morillon Th. Paris, 1897, p. 96. Male, aged 15 years. Pyemic abscess of a few days. Appendicitis operated on twenty-seven days before. Location, base of left lung, pos-

teriorly. Signs of cavity. Resection of 6 cm. of sixth rib on posterior axillary line; pneumotomy; 8 c.c. of sanguinal pus; drainage. Improvement twenty-three days after, wound healing; no more signs of cavity.

Case 51, 1891. Mategnon, Arch. gen. de Med., 1894-2-1, p. 162. Male, aged 22 years. Chronic abscess; hemoptysis; profuse expectoration; one and one-half years duration. Acute pneumonia. Location, right apex, forward; signs of cavity; ancient and firm adhesions; two negative exploratory punctures a long time before operation. A resection of 4 cm. of second rib; positive exploratory puncture; incision with thermocautery of 5 cm. of pulmonary parenchyma; a cavity opened; accidents of retention four days after second pneumotomy, after negative puncture at base of first cavity. Recovery after relapse, which necessitated a third pneumotomy; several hemoptyses; profuse expectoration; cicatrization in three months. Patient seen in six months after in good health.

Case 52, 1895. Berger, Soc. de Chir., 1895, p. 716. Abscess of the lung. Rib resection; pneumotomy with a cautery; incision 4 cm. in depth; no abscesses found, but the hemorrhage necessitates a tamponade and suspension of operation. Death several days after. Necropsy: The pulmonary incision is found just between two purulent cavities.

Case 53, 1895. Soc. de Chir., 1895, p. 733. Monod. Male, aged 35 years. Abscess at base of lung. Signs of cavity; adhesions. Resection of the seventh and eighth ribs; pneumotomy; cavity located higher up than had been thought; opened with thermo-cautery after two exploratory punctures; it had the volume of a walnut. Recovery.

Case 54, 1895. Quinke, Mittheil. aus Zrenzeber Med. Chir., 1895, p. 1; loc. cit., pp. 6 and 7, Tab. I, Obs. 7. Male, aged 23 years. Acute abscess three weeks after onset; profuse expectoration and hemoptysis; later bloody expectoration; nine weeks' duration. Pneumonia twelve weeks previous. Location, base of left lung, posteriorly; no signs of cavity. Incision. Application of ZnCl₂ paste in ninth rib intercostal space; eighteen days after resection of ninth rib, exploratory puncture; no cavity is found. Complete cure in six weeks; rapid retraction of thoracic wall.

Case 55, 1895. Quinke, Mittheil. aus Zrenzeber, 1895, dd. a. B., p. 1. Male, aged 33 years. Acute abscess of lung, two months duration. Pneumonia due to aspiration of mud. Location, base of left lung; no signs of cavity. Puncture; 300 c.c. of serous fluid. Sudden death ten days after puncture. Necropsy: Sero-purulent pleurisy and primary abscess of lower left lobe, opening into pleura bronchi; ecetasis and cicatrix of a healed abscess situated above first mentioned abscess; right-sided pneumonia.

Case 56, 1895. Ricard, Soc. de Chir., 1895, p. 689. Pyemic abscess mistaken for interlobular pleurisy. Location, base, posteriorly; no signs of cavity; partial adhesions. Resection of 10 cm. of eighth rib; incision; partial pneumothorax; abscess located higher and in the lung; is incised and drained. Recovery.

Case 56, 1895. Tuffier, Soc. de Chir., 1895, p. 766. Obs. 2. Male, age not given. Lung abscess; pneumonia. Incision without costal resection; complete pneumothorax focus could not be opened. Pyepneumothorax which was followed by empyema. Death one year later. Necropsy: Purulent pleurisy and abscess not opened.

Case 58, 1895. Valtou, Belgique Medicale, 1895, Vol. 2, p. 545. Male, aged 13 years. Abscess of lung; lung cavity; fetid expectoration; eighteen months duration; pneumonia. Location, base of right lung. Resection of the seventh, eighth and ninth ribs; lung apparently normal after several negative punctures had been made; pus was found; pneumotomy with thermo-cautery; after suturing lung to pleura partial cleansing of cavity; drainage. Death twenty days after from exhaustion.

Case 59, 1895. Webb, J. E., London Lancet, Vol. 1, 1895, p. 1140. Female, aged 27 years. Abscess of lung. Duration, one month. Maternal history of phthisis inflammation of lung in early childhood. No physical signs of cavity. Puncture; anterior axillary line, sixth interspace; twelve ounces of pus removed. Trocar and canula inserted into cavity just above angle of scapula, between it and vertical column, directed forward and outward; fourteen ounces of pus removed; drainage tube passed through canula; iodoform injected. Two months after operation discharge ceased; two and one-half months later fluctuation was detected in the fifth interspace below the nipple; incision made and pus evacuated; this sinus closed in a few days; ultimate recovery.

Case 60, 1896. Bushnell, Am. Jour. of Med. Sci., 1896, Vol. 112, p. 298. Male, aged 36 years. Abscess of the lung; interlobular pleurisy; several weeks' duration. Acute pneumonia; location, base; partial adhesions; three positive punctures in sixth interspace. Incision: in sixth interspace no adhesions at this level; partial pneumothorax without gravity; puncture of lung; pus is immediately under the visceral pleura. Rapid disappearance of pneumothorax; six punctures parietal and five punctures a little later. Completely cured; abscess discharged into bronchi; recovery in seven months.

Case 61, 1896. Esquerdo, Rev. de Cien. Med. de Barcel., 1896, Vol. 22, pp. 244-250. Male, aged 42 years. Lung abscess; pain in side and dipphulla cough; expectoration profuse; at first purulent, later putrid; slight hemoptysis; fourteen months duration. Exposure to cold; sailor. Right lung; signs of cavity; no pleural adhesions. Incision above seventh right rib, extending backward to axillary line; resected 10 cm. of rib; sutured lung to parietal pleura; explored with finger; induration found; thermo-cautery tip introduced into induration; cavity found and contents evacuated; packed with iodoform gauze; fourth day, cavity washed with warm boric acid; it came through into wound; solution came through into month; irrigation repeated many times; after eight days drainage tube put in. Cough and expectoration became less after operation; cavity became swollen; at end of forty days, no discharge from tube and patient has no cough or expectoration; four days after this he had a slight hemoptysis; ultimate recovery.

Case 62, 1896. Luther, Australian Med. Gaz., 1896, Vol. 15, p. 344. Male, aged 37 years. Lung abscess opening into a bronchus; duration, six weeks. Chill and pain in left side; located in left lung; no positive sign of cavity; pleural adhesions. Incision over seventh rib; center of incision midway between spine and wound in axillary line; part of seventh rib resected; adherent pleura; lung easily broken down by finger; one-half pint of pus and debris; cavity douched with 40 per cent. of creolin; drainage. Recovery; great relief. Cough and expectoration ceased; night sweats did not recur; temperature fell to 100, then to normal five days after operation; gained strength rapidly; perfect recovery.

Case 63, 1896. Sims, Med. Rec., 1896, Vol. 49, p. 500. Lung abscess. Incision and drainage. Recovery.

Case 64, 1897. Andrews, in Morillon de Paris, 1897, p. 71. Male, aged 17 years. Lung abscess; duration several months; location, base of left lung; pleural adhesions. Puncture, 500 c.c. of pus. Resection of second rib, posteriorly; pneumotomy; enlargement of the puncture wound. Rapid recovery; seen sixteen years later; cured.

Case 65, 1897. Andrews in Morillon de Paris, 1897, p. 72. Female, aged 35 years. Abscess of lung; several months duration. Angio-cholecystitis; cholecystenterostomy after mercury. Location, right lobe, posteriorly; no signs of cavity; pleural adhesions. Punctures of lung and liver negative. Resection of two inches of seventh rib posteriorly; puncture negative; trocar inserted in all directions; at last reached a purulent cavity internally close to the vortical column; pneumotomy with cautery; 150 c.c. of pus. Recovery in ten months.

Case 66, 1897. Carl Beck, N. Y. Med. Jour., 1897, Vol. 66, p. 207. Male, aged 31 years. Duration, three months. Pneumonia when 10 years of age; in November, 1885, pleuro-pneumonia followed by cough and fetid expectoration. Location, right side anteriorly and below; signs of cavity. Incision over ninth rib from post axillary line to transverse process of ninth dorsal vertebra after right eighth and tenth ribs were resected; pleura was packed with aseptic gauze; needle pushed into lung; cavity entered; offensive pus aspirated with needle; opening dilated and packed with gauze. Considerable cough and expectoration after operation; patient improved rapidly; wound closed two months after operation.

Case 67, 1897. J. Curnow, London Lancet, 1897, Vol. 2, p. 1188. Male, aged 37 years. Empyema and abscess of lung; twelve days duration. Acute pneumonia; apex of left lower lobe; signs of cavity not certain; pleural adhesions. Positive puncture below angle of left scapula; twenty-four ounces of odorless pus removed. Incision in eighth interspace, median axillary line; twenty-four ounces of pus removed; drainage tube. Patient died next day. Necropsy: Right lung showed congestion and bronchitis of lower lobe of left lung; adherent pleural pneumonia abscess; cavity 2 cm. from apex, posteriorly.

Case 68, 1897. Edwards, London Lancet, Vol. 2, 1897, p. 1583. Female, aged 21 years. Lung abscess of two months duration; pleuro-pneumonia of right side; no positive signs of cavity. Puncture in the eighth interspace below angle of right scapula; two and one-half to three inch cavity was revealed; offensive pus; incision two and one-half inches long over ninth rib below angle of scapula; one inch of ninth rib resected; trocar and canula put into cavity and opening enlarged with finger and forceps; rubber drainage tube. Marked improvement; three days later temperature increased and condition was critical; one week after operation improvement again took place. Perfect recovery six weeks after operation; wound closed.

Case 69, 1897. De M. Moir, London Lancet, Vol. 1, 1897, p. 105. Male, aged 34 years. Liver abscess ruptured into the lung; liver abscess had existed about ten months. Etiology: Malarial perineal abscess and gonorrhea; obstructed liver abscess breaking into lung. Location, right lung in axilla; signs of cavity. Liver abscess incised and drained through the sixth interspace about two months before lung abscess was opened; mass far back in right axilla over fifth rib; one inch of fifth rib resected; counter opening in front in fourth space below nipple, opening up a secondary cavity which communicated with the first, also with liver abscess; drainage tubes in both incisions; taken out after seventeen days; wound closed rapidly. Discharge and expectoration diminished. Gradual improvement and ultimate recovery.

Case 70, 1897. Rontier, Soc. de Chir., 1897, p. 138. Lung abscess; no signs of cavity; pleural adhesions. Pneumotomy after costal resection. Patient getting better when observation was reported.

Case 71, 1897. Ballington, Arch. Gen. de Med., 1887, Vol. 20, p. 465. Male, aged 6 years. Pleurisy and lung abscess. Pneumotomy; drainage of pleura and abscess cavity. Recovery.

Case 72. Maydill, Jour. Amer. Med. Assn., Male, aged 29 years. Lung abscess of one month's duration; rupture of lung, posteriorly; signs of cavity; partial pleural adhesions. Resection of rib over area of dullness, near angle of scapula; cautery used to open cavity; escape of fetid fluid; masses of gangrenous lung discharged. Pulmonary edema and pneumonia of sound lung followed recovery. Cavity slowly diminished in size.

Bronchiectasis.—A dilatation of a bronchus may be cylindrical or ampullar, local or diffuse. (Grawitz.) Etiologically it may be a congenital defect or anomaly. (Welch.) It may be intrinsic, the result of inflammation, necrosis, softening and dilatation, with retention of secretion in the bronchi; extrinsic, the result of contraction of the lung tissue or pleuritic adhesions. The ampullar variety when localized is the one which concerns the surgeon. The universal bronchiectasis, or the entire involvement of the bronchial tree (Osler), should not be treated surgically. Habershon⁵² reports autopsy with multiple gangrenous bronchiectases of all lobes of both lungs. Pathologically the wall of the bronchus may be attenuated and its mucosa lined with pavement epithelium; more commonly it is ulcerated, with the lung tissue in the neighborhood involved in an inflammatory infective process. As surgical bronchiectasis is secondary to other pathologic conditions its symptoms are usually intermingled with those of the original disease. In the ampullar variety, however, the cough and expectoration are distinctive. The patient will pass many hours without coughing, followed by a violent attack with the expectoration of several drams or even ounces of a grayish, purulent fluid, with a sour and sometimes fetid odor; the microscope reveals crystals of fatty acids, occasionally those of hematoidin, and in tubercular cases bacilli. The physical signs are those common to cavities; exploratory puncture gave positive results in 50 per cent. of the cases reported. (Terrier.) Endeavor has been made to disinfect and medicate cavities of this class through inhalation. This up to the present has not been very successful. Hesse, of Schwartzberg, showed that dust does not reach beyond the third division of the bronchus. Dr.

⁵² Lancet, London, April, 1894, p. 1012.

Homer W. Thomas has made some excellent and interesting experiments in this line; he showed that vapors were carried into the alveoli themselves and demonstrated in one of the cavities on which I operated that the cavity could be filled with a sterilizing vapor.

Operation.—The sacculated is the only variety that admits of surgical treatment, and in this we have again the difficulty of differentiating between a number of small cavities closely situated and a large cavity. This was illustrated in a case to be related subsequently. The great obstacle in the surgical treatment of this class of cases is our defective localization, and while the radiograph shows distinctly the outline of large cavities it is not yet practical with small ones. Operation should be the same as that performed for abscess, though not more than two ribs should be resected. Adhesions were present in 84 per cent. of the cases operated. Digital exploration of the lung may aid in the localization of the cavity. The exploratory needle is also of service; when located the scalpel should be used to open the abscess and the cavity should be tamponed with iodoform gauze. Osler⁵³ cites a case of death following the operation for bronchiectasis with fetid bronchitis. Hofmokl⁵⁴ strongly favors the opening and drainage of these cavities and reports 42 cases, 14 cures, 3 fistulae, 24 deaths, 1 result unknown. The results of operations in this class of cases have been very unsatisfactory. Roswell Park⁵⁵ collected (including Truc's) 23 cases with 9 deaths. Of 38 cases collected by Tuffier there were only 9 cures; certainly not a tempting inducement for incision and drainage. Leser,⁵⁶ of Halle, favors this operation. I have collected histories of 44 cases of bronchiectatic cavities that were operated upon; of these 25 recovered, 19 died. Of the 19 deaths, 11 were from undetermined causes, 1 from chloroform syncope, 1 from acute bronchitis, 2 from collapse, 3 from brain abscess, 1 from hemorrhage. We will await with interest the results of local compression after the removal of the thoracic wall as a treatment for this class of cases, as well as the results from artificial pneumothorax either of which I believe is preferable to drainage.

Case illustrating local compression, referred by Drs. Homer W. Thomas and Geo. W. Johnson: Maggie C., aged 48, admitted to Cook County Infirmary October, 1897, suffering from pulmonary tuberculosis; bacilli demonstrated; evening temperature, 102–103°. Physical examination reveals consolidation of both apices; rales universal; amphoric respiration demonstrated in left upper lobe anteriorly; the cavity is apparently large, extending from the first interspace to the third in the anterior axillary line, and having a transverse diameter of about three inches; the most pronounced signs are at the lower margin of the second rib; there is also evidence of a cavity in apex of left lower lobe posteriorly. The belief was that the cavity was very large.

Diagnosis.—Bronchiectatic cavities (tubercular).

Operation.—November 14, 1897, resection of three inches of the second rib, left side, without opening the pleural cavity; found pleura adherent; Paquelin cautery was used and a small cavity the size of a walnut was opened; this was packed with iodoform gauze and the lung was compressed. The patient was in good condition on the table; six hours after the patient's temperature dropped to 95°, pulse became extremely weak and 160 beats a minute. Active stimulation was resorted to and in eight hours she rallied perfectly. The packing was not disturbed for three days, when it was removed; it was thoroughly saturated with pus and blood. The dressing was changed daily thereafter. The quantity of discharge was excessive at first and gradually diminished; the daily temperature was 102° in the evening and gradually dropped from that until it reached 90°. The improvement, diminution of discharge, increased appetite and lowered temperature continued

for about three weeks. The temperature began to rise; the night sweats reappeared, the expectoration rapidly increased, evidences of the formation of cavities in the right lung appeared and the patient grew rapidly worse. The cavity in the left lung was granulating and the discharge had almost ceased. The patient died rather suddenly on December 15, having shown no signs of approaching dissolution to within half an hour of her death.

Postmortem revealed multiple cavities in the upper lobe of the left lung and numerous cavities in the upper and lower lobes of the right lung; there was an acute necrosis and gangrene of the walls of the cavities in many places, which probably accounted for the sudden death. The cavity which had been drained was almost obliterated, cicatrized and covered with healthy granulations. There were numerous small cavities in close proximity to this which caused the error in the estimate of the size of the cavity at the time of operation. (History furnished by Dr. Clara Ferguson). Bronchiectatic cavities operated, forty-six.

Bronchiectatic Cavities from 1873 to 1897.

Case 1, 1873. Mosler and Huter, *Klin. Woch.*, 1873, p. 43. Male, aged 49 years. Signs of bronchial dilatation of five years' standing. Incision at the upper border of the third rib to 5 cm. from the right border of the sternum; opening of the pulmonary cavity; drainage. Recovery; temporary improvement; death three months later, Oct. 5, 1873. Necropsy: Bronchiectatic cavity of the right upper lobe; amyloid degeneration of the viscera.

Case 2, 1875. Rielus, *Klin. Clin. de la Pitie*, 1894, p. 39, and *Congress de Clinique*, 1875, p. 62. Male, aged 50 years. Incision at the level of the third interspace; resection of 8 cm. of third rib. Recovery; amelioration; fistula persistent and accidents of retention; Eslander's operation two months later; death during chloroform anesthesia.

Case 3, 1882. W. Koch, *Deutsch Med. Woch.*, 1882, p. 440. Male, aged 24 years. Signs of cavity in the right lower lobe; four years' duration. Resection of the sixth rib; the pleura adherent; opening with cautery of a large cavity the size of a child's fist situated three finger breadths from the surface of the lung and into which several large bronchi open. Second operation, resection of the eighth rib; no large cavity. Third operation, opening of a large cavity between the eighth and ninth ribs. Recovery with marked improvement.

Case 4, 1882. W. Koch, *Deutsch Med. Woch.*, 1882, p. 441. Male, aged 24 years. Signs of cavity in right lower lobe with abundant fetid expectoration; 800 to 1000 c.c. in twenty-four hours; duration, four years. Resection of four inches of fifth rib; incision, oblong, with cautery; opening of cavity the size of a fist; expression of the lung in this cavity and opening of a second cavity the size of a child's head, from which escaped the little fetid fluid. Death seven days later, July 22, 1882; collapse. Necropsy: Phlebitis of the portal vein; amyloid degeneration of the viscera; broncho-pneumonia of the left lower lobe.

Case 5, 1882. Mosler and Huter, *Berlin M. A. Cong. for Med.*, Vol. 2, 1882, p. 87. Pneumotomy without rib resection; opening of a bronchiectatic cavity; drainage. Recovery without fistula; cure maintained fifteen months; death March, 1876; general tuberculosis. Necropsy: Amyloid degeneration of viscera.

Case 6, 1882. Williams, *Marshall Lancet*, 1882, Vol. 2, p. 1107. Male, aged 40 years. Bilateral pneumonia with right bronchiectasis; abundant fetid expectoration; duration, one year. Vertical incision from fourth to fifth ribs; puncture of the lung with a large trocar; escape of air and fetid pus; drainage. Recovery; moderate improvement; death July 5; cerebral accidents. Necropsy: Total adhesion of right pleural; fistula between fourth and fifth ribs; numerous bronchial dilations of the anterior portion of the lung, the larger, the size of an orange, has been opened; no other bronchial dilations; abscess of the right cerebral hemisphere.

Case 7, 1883. Bull, *North Med. Archives*, 1883, Vol. 15, p. 17. Male, aged 25 years. Chronic general bronchitis with signs of cavity of right base; retraction of the thorax; duration, seven years. Incision in the seventh interspace with cautery; the lung examined with the finger; no cavities of large size; escape of fetid gas; hemorrhage; tamponade. Recovery; amelioration; several exploratory punctures without results; death one month later. Necropsy: Right pleural adhesions; multiple bronchiectases; no large cavity; interstitial pneumonia in the left; pleurisy and bronchial dilatation.

Case 8, 1883. Kazarowski, *Deutsch Med. Woch.*, Vol. 9, No. 29, p. 432. Female, aged 25 years. A bronchial dilatation or purulent pleurisy. Resection of the sixth rib; pneumotomy; opening of a large cavity. Recovery; purulent pleurisy, consecutive.

Case 9, 1883. Laden, *Deutsch med. Zeitung*, No. 28, 1883, p. 375. Patient expectorates nearly one-half liter of fetid sputa and not containing portions of lung substance; cavity in lower portion of left lung or pleura; general condition bad. Incision without narcosis; large amount of fetid fluid. Recovered; two days later resection of rib; antiseptic irrigation; condition becomes better; improvement slight; fistula remains.

Case 10, 1884. Albert Wiener, *Med. Press*, July 6, 1884, p. 855. Bronchiectatic cavity in lower left lobe. Opened with thermo-cautery. No result.

Case 11, 1884. Biss and Marshall, *Med. Times and Gazette*, 1884, Vol. 1, p. 747. Male, aged 32 years. Bronchiectasis of the right base; bacteriologic examination negative; duration six months. Operation between the tenth and eleventh ribs; a puncture of the pleura; escape of air and bloody fetid liquid; drainage; irrigation with permanganate not tolerated. Death eighteen days later; cerebral accidents. Necropsy: Multiple bronchiectasis of the right base, of which the larger have been opened; the left lung normal; two brain abscesses.

Case 12, 1884. Tausenstein, *Cent. f. Chir.*, 1884, p. 290. Male, aged 37 years. Fetid, abundant expectoration; duration several years. Resection of four inches of the anterior portion of the eleventh rib; puncture of the lung with a trocar; dilatation of the tract; large cavity with resilient walls; insertion of drain. Recovery. According to Quinke this patient met death from hemoptysis.

Case 13, 1885. De Crenville, *Rome Med. Suisse Romande*, 1385, Vol. 5, p. 462, obs. 1. Male, aged 50 years. Sacciform excavation of right lower lobe; puncture with a large trocar. Recovery. Death two months later; mania; refused nourishment. Necropsy: Pleural adhesions; a regular cavity surrounded by sclerotic tissues; no tuberculosis.

Case 14, 1885. De Crenville, *Ibid.*, obs. 2. Cavity of the left base; duration, four years. Puncture with a large trocar; dilatation. Recovery. Death nine weeks later. Necropsy: Irregular excavation of the left lower lobe; kidneys and liver sclerotic.

⁵⁵ Ann. Surg., St. Louis, 1887, v, 385.

⁵⁶ Lancet London, March 9, 1891.

Case 15, 1886. Rochelt, Wiener Med. Presse, 1886, p. 1264. Male, aged 54 years. Bronchiectasis of the right lower lobe; examination for bacilli negative; duration three years. Operation in two sittings; first is resection of sixth rib; second is pneumotomy forty-eight hours later with the cautery; cavity the size of a hen's egg; drainage. Recovery.

Case 16, 1886. Rochelt, Wiener Med. Presse, No. 37. Female, aged 36 years. Fetid expectoration; fever; abscess formation at the base of left lung with excavation in the sixth interspace; incision for empyema. No amelioration of general symptoms; incision made in lung; pus and blood escaped; patient had an attack of hemoptysis; iodoform gauze tampons inserted; wound washed out next day; debris was taken out; iodoform tampons. Fever abated; cough and fetid expectoration ceased; complete recovery of gangrenous excavation inside of four weeks.

Case 17, 1886. Williams and Godley, Brit. Med. Jour., 1886, Vol. 1, p. 500. Male, aged 67 years. Bronchiectasis of the left base; duration two years. Incision at the level of the eighth interspace. Recovery. Death from cardiac syncope one year after operation.

Case 18, 1886. Williams and Godley, Med. Chir. Transactions, 1886, Vol. 69, p. 234. Female, aged 21 years. Multiple bronchiectasis at the level of the sixth and seventh interspace. Resection of an inch of the seventh and eighth ribs; puncture of the lung; drainage. Recovery; amelioration.

Case 19, 1887. Benson and Godley, Lancet, 1887, Vol. 1, p. 716. Male, aged 55 years. Signs of cavity upon the left in the axillary line. Incision in the tenth interspace. Death three days later. Necropsy: Multiple dilations of the whole left lower lobe; no large cavity; fatty degeneration of the heart; nutmeg liver.

Case 20, 1887. Godley and Powell, Lancet, 1887, Vol. 1, p. 716. Male, aged 35 years. Duration of symptoms one year. Death from chloroform syncope at beginning of operation. Necropsy: Bilateral general bronchial dilatation.

Case 21, 1887. Godley, Lancet, 1887, Vol. 1, p. 717. Female, aged 29 years. Bronchiectasis limited to the left base. Resection of the tenth rib; opening of a bronchial cavity; drainage. Recovery. Not seen after leaving hospital.

Case 22, 1887. Stewart, Brit. Med. Jour., 1887, p. 179, and 1893, Vol. 1, p. 1147. Male, aged 27. Signs of cavity at angle of left scapula; duration nine years. Incision; rib resection; opening of a pulmonary cavity; counter-opening and drainage. Recovery.

Case 23, 1888. Hoffmohl, Soc. Imp. Roy. des Med. de Vienne, January, 1888. Male, aged 32 years. Rib resection; incision of the lung with cautery; opening of a cavity located at the depth of 7 cm.; escape of air. Recovery.

Case 24, 1889. Mackey, Brit. Med. Jour., 1889, Vol. 2, p. 660. Male, aged 20 years. Signs of cavity of right base; duration four years. Intercostal incision, pleuro-pulmonary adhesions; puncture; operation suspended on account of cough; eight days later incision of the lung; opening of a cavity filled with pus. Recovery. Death six weeks later. Necropsy: Multiple cavities occupying the whole of the right lower lobe; focus of pulmonary gangrene in the left lower lobe, but no bronchial dilatation of this side.

Case 25, 1889. Mosler and Volk, in Hortwin Inaug. Dissert., Griefswald, 1889. Male, aged 13 years. Bronchiectasis of the left lobe. Resection of the third rib; opening of a cavity the size of an apple; counter-opening between the ninth and tenth ribs at the level of which we came upon a cavity containing one and one-half liters of pus; pleural adhesions. Death seven days later.

Case 26, 1890. Osler, Johns Hopkins Bulletin, Vol. 1, 1890. Male, aged 60 years. Had pneumonia several times in many years; has had pain in side and chest, spitting blood at times; cough and fetid expectoration; clubbed fingers; wasted left side of chest retracted; amphora sounds; temperature 98 to 101. Resection of portion of fourth and fifth ribs; a series of cavities opened; these were packed with iodoform gauze. Patient sank after operation and died on third day. Necropsy: General bronchiectasis; no tuberculosis.

Case 27, 1891. Kroke, Munich Med. Woch., 1891, p. 399. Male, aged 48 years. Bronchial dilatation of the left base; duration several years. Exploratory punctures; escape of pus; rib resection; incision; no pleural adhesions; pneumothorax makes the examination of the lung impossible. Death several hours later. Necropsy: Multiple bronchiectatic cavities; large cavity in the left lower lobe.

Case 28, 1891. Itaache, Mag. forger, 1891, No. 4, in Quincke Mittheil. aus d. Grenz. gebdaul-wchir, 1895, Vol. 1, p. 44, obs. 7. Male, aged 47 years. Sacciform bronchiectasis; signs of cavity; duration six years. Exploratory puncture; resection of 5 cm. of the eighth rib in the axillary line; no pleural adhesions; suture of the lung to the lips of the wound; eight days later opening of a cavity with cautery. The immediate result was amelioration. Persistence of a fistula; expectoration reduced from 900 to 100 c.c.; Death nine months later from meningitis (abscess of the brain).

Case 29, 1892. S. Conpland, Lancet, 1892, Vol. 2, p. 869. Female, aged 16 years. Cavities of the left base; no bacilli; duration two years. Operation by Pence-Gould; two exploratory punctures, below and above the eighth rib, May 10; May 17, diffuse swelling at level of puncture; incision; opening of pulmonary cavity; resection of eighth rib. Death from chloroform syncope. Necropsy: Saccular dilations of the bronchi in the left lower lobe; another bronchial dilatation of the left upper lobe and the right lung.

Case 30, 1893. Hoffmohl, Wiener Med. Presse, 1893, April 30. Male, aged 43 years. Sign of cavity in right apex. Incision with cautery in the second interspace; escape of pus; drainage. Recovery.

Case 31, 1895. Reclus, Klin. Clin. de la ditie., 1894, p. 39, Cong. de Clin., 1895, p. 62. Male, aged 50 years. Incision at the level of the third interspace; resection of 6 cm. of third rib. Recovery. Amelioration; fistula persistent and accidents of retention; Eslander's operation two months later; death during chloroform anesthesia.

Case 32, 1895. Biondi, Clinica Chir.-Milaro, 1895, Vol. 3, p. 475. Male, 26 years. Left interstitial pneumonia, putrid bronchiectasis; dry adhesive pleurisy and the existence of a superficial cavity in the lower part of the scapular region. Pneumectomy performed. Death fifteen hours later. Necropsy: Postmortem purulent pleurisy from escape of bronchiectatic fluid into pleuric cavity during the operation; multiple bronchi dilatations.

Case 33, 1895. Ahrona, loc. cit., ibid. Bronchiectasis; fever and abundant expectoration. Pneumectomy performed. Recovery; temporary amelioration; reappearance of the irregular fever and expectoration several days after the operation.

Case 34, 1895. Quincke, Mitt. aus ten Granzg. der Med. Chir., band 1, H. T. 1, 1895, p. 15, obs. 2. Male, aged 25 years. Multiple bronchiectasis; signs of cavity upon the left posteriorly and at the base; expectoration amounted to 150 to 200 c.c.; duration two months. Incision in eighth interspace; three applications of paste of chlorid of zinc; eighteen days later resection of the ninth, tenth and eleventh ribs; application of the paste of chlorid of zinc four days later; exploratory puncture; pus; incision with cautery. Recovery; Patient left in August, 1896, and returned to his work.

Case 35, 1885. Quincke, loc. cit., p. 41, obs. 12. Male, aged 49 years.

Cylindrical bronchiectasis of left base. Application of paste of ZnCl₂; four weeks later resection of 4 cm. of tenth rib; no cavity; opening of a bronchiectasis. Recovery; amelioration; left hospital five months later.

Case 36, 1895. Quincke, loc. cit., p. 17, obs. 3. Male, aged 34 years. Multiple bronchiectasis of left base; retraction of thorax; no signs of cavity; duration several years. Incision in eighth and ninth interspace; application of zinc chlorid; resection of ninth and tenth ribs; wall incised with cautery; Zn. Cl. 2 on lung. Recovery; amelioration; patient escaped tuberculosis.

Case 37, 1895. Quincke, loc. cit., p. 18, obs. 4. Male, aged 36 years. Bronchiectasis of left base, secondary to a chronic bronchitis; twelve years' duration. Resection of ninth rib; Zn. Cl. 2 applied without result; later resection of the tenth rib. Recovery; amelioration; death two years later.

Case 38, 1895. Quincke, loc. cit., p. 27, obs. 7. Male, aged 66 years. Bilateral multiple bronchiectasis with sacciform dilatation in left base; signs of cavity; duration four years. Resection of 7 cm. of ninth rib; exploratory puncture without result; no pleural adhesions. Death; collapse before the incision of the cavity. Necropsy: Amyloid degeneration of viscera.

Case 39, 1895. Quincke, loc. cit., p. 34, obs. 9. Male, aged 12 years. Multiple cylindrical bronchiectasis of whole right lung; no signs of cavity; duration three and one half years. Resection of second, third, eighth and ninth ribs; exploratory puncture. Recovery; no amelioration.

Case 40, 1895. Quincke, loc. cit., p. 32, obs. 8. Female, aged 42 years. Bronchiectasis of left base; sacciform and cylindrical; no signs of cavity; five applications of Zn. Cl. 2. Resection of tenth rib; incision with cautery. Death four days later; collapse. Necropsy: Small bronchial dilations; large cavity in left apex.

Case 41, 1895. Quincke, loc. cit., p. 35, obs. 11. Male, aged 31 years. Sacciform bronchiectasis of left base; no signs of cavity or pneumonia; duration five years. Incision; application of Zn. Cl. 2; resection of 4 cm. of tenth rib; incision of the cavity; drainage. Recovery; fistula. Death during second operation; hemorrhage and entrance of air into pulmonary veins.

Case 42, 1895. Quincke, loc. cit., p. 37, obs. 11. Male, aged 54 years. Sacciform bronchiectasis of left base. Three applications of Zn. Cl. 2 paste; resection of eighth, ninth and tenth ribs; pleural adhesions. Death one month later from hemorrhage.

Case 43, 1895. Walter, Congress de Chir., 1895, p. 101. Female, aged 26 years. Chronic bronchitis with bronchial dilatation of entire left lung; purulent pleurisy existed in lower portion of left pleura, probably consecutive to a point of pulmonary gangrene, with pleuro-bronchial fistula. Resection of seventh and eighth ribs posteriorly; pleural adhesions very large; resection of eighth and ninth ribs; opening of an enormous cavity; tamponade with gauze and sponges. Recovery without fistula after secondary thoracoplasty.

Case 44, 1896. Piorro, Selbet in de Agincourt thesis de Paris, 1896, p. 73. Male, aged 45 years. Bronchiectasis of left base; expectoration reaching as high as one and one-half liters. Resection of 5 cm. of the seventh rib; opening of a large cavity the size of a nut, surrounded by other small cavities at a depth of 5 to 6 cm.; escape of fetid pus; drainage. Recovery; marked improvement. Death twenty months later.

Case 45. Gerard Marchant in Guilmont and Herbert, Soc. Anatomy, 1896, p. 552. Bronchiectasis of right base. Resection of seven to eight cm. of fourth rib; resection of third rib; cavity located higher than had been supposed; opening of a cavity the size of a hen's egg; walls of cavity bleeding; two forceps left attached. Amelioration. Death four months after the operation. Necropsy: Right lung, except at a point in the upper lobe, is entirely destroyed and perforated by irregular cavities, the larger of which are the size of a walnut.

Case 46, 1896. Wills, Lancet, 1896, Vol. 1, p. 1563. Unilateral bronchiectasis. Rib resection; several punctures; negative; pleural adhesions. Death on the eleventh day. Necropsy: Unilateral cylindrical bronchiectasis without a large cavity.

Case 47, 1897. Coppehkov, Wrathe, 1897, No. 6. Female. Bronchiectasis with hemoptysis. Pneumotomy; opening pocket the size of a nut. Recovery of hemoptysis; several days later second pneumotomy; opening of several cavities. Cure maintained several months.

Case 48, 1897. Nelaton in the Buisard, Paris, 1897. Male, aged 34 years. Repeated bronchitis during past four years and secondary bronchiectasis of left base; interlobar pleurisy. Incision in the sixth interspace; no resection of ribs; opening of a cavity; drainage; irrigation incites cough. Death twelve days later; coma. Necropsy: Multiple dilations of bronchi of left lower lobe; large cerebral abscess occupying the frontal and cerebral lobes; but one bronchiectatic cavity opened.

Case 49, 1897. Nelaton in the Buisard, Paris, 1897. Female. Bronchiectasis. Pneumotomy performed. Recovery; amelioration for six months; recurrence.

Gangrene of the Lung.—Gangrene of the lung may be diffuse or circumscribed. It has four distinct stages: Necrosis, putrefaction, demarcation and elimination, and reparation. It is most frequently a result of acute pneumonitis. Andral found it present in 3.3 per cent of post mortems for pneumonia; Hughes found it in over 10 per cent. in Guy's Hospital (Paget). In place of resolution taking place at the proper time there is a death of lung tissue. The lung tissue is unable to react from the destructive effect of the infection by reason either of its character or intensity, and as a consequence gangrene results. Gangrene may be the result of a foreign body in the bronchus, an inhalation infection, a septic embolus, necrosis of an infarct, etc. It may be the result of an extension of infection from a bronchiectatic or abscess cavity or from a putrid bronchitis, when it is often multiple, as shown in a case by Walter D. de Jersey.⁵⁷ It may result from perforation into the lung of abscess cavities, as

⁵⁷ Lancet, London, Jan. 21, 1892, p. 27.

mediastinal or subphrenic, from perforation of the esophagus, with foreign bodies, as in a case reported by Pasteur, London, and operated by Bilton Pollard, in which a communication was found between the esophagus and the bronchus at its bifurcation; a gangrene of the right lung was produced; it was treated by double drainage. Gangrene occurs most frequently in the lower lobe, and is most often situated near the surface of the lung, next near the center and less frequently near the interlobar septum. (Tuffier.) After necrosis it may undergo rapid decomposition, depending upon the presence of saprophytes. In the diffuse variety an entire lobe may be involved. (Trier.) The separation of the slough is slow; the sequestrum may be expelled through the bronchus or through the chest wall by extension of the necrotic processes. The gangrenous areas are multiple in 15 per cent. of the cases.

Diagnosis.—The symptoms of gangrene of the lung are usually very pronounced, though they may merge from those of a severe pneumonia. When the typhoid mutterings, nervous prostration and evidence of intense intoxication continue beyond the usual limit for a pneumonia, gangrene should always be suspected. If it be diffuse, the breath and expectoration soon become offensive; the latter is a brown, frothy, muco-purulent fluid; it is often profuse; the amount expectorated in one seizure of coughing is some index to the size of the cavity; there is probably no odor so offensive as that of the breath in gangrene of the lung. In the circumscribed variety the gangrenous cavity may not communicate with the bronchus, in which case there would be no odor. There is usually circumscribed dullness but rarely edema of the chest wall. Exploratory puncture gives a foul-smelling fluid or a very offensive gas. This procedure is not devoid of danger. Gangrene of the tract of the needle and gangrene of the wall of the chest with emphysema followed in case of E. Bull; incision and drainage were resorted to with recovery. Errors in localization of cavities have been of frequent occurrence with the best diagnosticians. Barry called attention to this in 1726. Tuffier found exploratory puncture positive in but two-thirds of the cases. He emphasized its dangers and said it should be restricted to the time of operation. Lejous⁵⁸ removed the eighth, ninth and tenth ribs and detached pleura, made digital inter-pulmonary exploration for a case of gangrene, presumably of the lower lobe with negative result; the patient succumbed, and post mortem showed the gangrene in the upper lobe. In another case in which he made inter-pulmonary palpation he succeeded in locating the induration and opened a cavity near the spine. He favors this method. Dr. Routier,⁵⁹ Paris, favors digital palpation, and located in this manner an inter-lobar abscess ten centimeters from the surface of the lung.

The following diseases, bronchiectasis, fetid bronchitis and gangrenous pleurisy may be confounded with gangrene. The history aids very much in the differential diagnosis, while the physical signs and the result of exploratory puncture may be the same in both cases. Under medical treatment the mortality of this disease is upward of 80 per cent. Surgery has reduced this mortality somewhat, although it is still great. Sonnenberg says that in seventy-four operations 35 per cent. recovered. Langenbeck oper-

ated successfully as early as 1879. (Gluck.) The surgical treatment of gangrene received its greatest impetus from Bull, Copenhagen, who made incision and drainage a recognized surgical procedure; his suggestions and conclusions have scarcely been improved upon. I therefore quote the following: "Limited pulmonary gangrene recovers without operation or puncture; extensive gangrene cannot be cured by bronchial drainage or aspiration, as the necrotic portions cannot get out; free incision should be made when gangrene is diagnosticated. If cavities are multiple, more than one opening may be necessary; operation is the only therapeutic efficient; pleuritic adhesions are an essential condition; vibration of needle with puncture is not a reliable negative symptom, nor absence of vibration positive of existing adhesions." Thomas Williams in 1877 diagnosed pneumonia followed by abscess and operated; patient died of pneumonia. When this was reported, Thompson, Bryant and Mamder favored this operation in discussion: Douglas Powell opposed it. Lowson reported a fatal case. Berkely Hill Sedgwich and S. C. Smith reported recoveries; the latter gave as indications for operation: 1, in cases where the gangrenous cavity is imperfectly drained through the bronchus; 2, where too much irritation is produced from the discharge; 3, in rapid emaciation; 4, unquestionable signs of cavity present.

The consideration of the results obtained in operations for gangrene shows a marked improvement as time has advanced, from Truc's cases, 1879 to 1884, 13 operations, 3 cures, 2 relieved and 2 on the way to recovery, 6 deaths. To those of Reclus, 1885 to 1895, 14 operations, 11 cured, 1 improved and 2 deaths.

Chloroform is the best anesthetic. (Tuffier.) The Schleich method of local anesthesia is good, and I consider it indicated here more than anywhere else. The question has been raised, should the operation be performed immediately or should we wait for certain pathologic changes to take place? The rules advanced in favor of delay are: 1, we should not operate until liquefaction of the slough has taken place; 2, we must be sure adhesions are present; 3, we must remember that circumscribed cases recover of themselves. The latter is the only rule of significance; when the abscess is small and there is free expectoration with the absence of toxic symptoms, time may be given with the hope of recovery without operation, though the sequestrum is rarely ejected through a bronchus. It must not be expected in the early stage that a cavity will be found; at this stage it will be a succulent, boggy mass, with very offensive odor; the mass should be freely incised for drainage, but no effort should be made at excision. The gangrenous cavity may have large vessels traversing it in which thrombosis has not taken place. Runneberg,⁶⁰ Fenger and Hollister⁶¹ were early and strong advocates of the free incision and ample drainage.

It is not necessary to wait for the separation of the slough before operating, as the danger of retention and the extension of the process increases as time advances: there is little danger of operating too soon, as the process is usually advanced before the diagnosis is made; neither is it necessary to wait for adhesions. The pleural cavity is most always infected and should be freely drained; recoveries in the absence of adhesions are reported by Krause, Paget, Reclus and others. When the gangrene

⁵⁸ Paris Med. Week, February, 1897, p. 91.

⁵⁹ Paris Med. Week, Feb. 26, 1897, p. 97.

⁶⁰ J. W. Runneberg, Helsingfors, Dent. Arch. f. Klin. Med., 1887, xli.

⁶¹ Am. Jour. Med. Sci., Philadelphia, 1881, Vol. xxxii, p. 370.

is situated high up it is very desirable to have adhesions, and unless they exist at the time of operation they should be induced by exposure and tampon or suture after the method of Péan, Roux and Godlee. The latter reports a case in which he adopted this method.⁶² It is desirable to open into the most dependent portion of the cavity, as it allows of better drainage and prevents the escape of pus into the bronchus, though it contributes little to the healing, as this is accomplished by cicatricial contraction. If the gangrene be in the depth of the lung, the pulmonary tissues should be freely incised, hemostasis secured and the surface protected by the application of the Paquelin cautery. The trocar and canula are not to be used in gangrenous cases, as they do not admit of sufficient drainage and are likely to be occluded by the slough. Injections of disinfecting material have proven a failure and should not be used. O. Hewdke, of Warsaw, used various injections in four cases without a cure.⁶³ If the operation be performed early the question arises, Shall the necrotic portion be excised, or merely incised and drained? The principles of surgery governing this appear to be the same as those governing gangrenous tissue in other portions of the body, *i. e.*, the sphacelus should not be excised; it will separate at the line of demarcation. The auto-separation appears to have an additional advantage, as it insures the thrombosis of the vessels and lessens the liability to hemorrhage in a location in which the surgeon is not entirely master of the situation. When the sphacelus is detached, it should be carefully removed at the time of operation. The cavity should not be irrigated, particularly if it communicate with a bronchus; large incision and free drainage is all that is necessary. The period of time which is required for the separation of the slough is indefinite. I have found in my experiments that pressure necrosis of the lung with separation of the stump after ligature takes place very slowly; it requires ten to twelve days, which would indicate that the line of demarcation forms slowly. The length of time required for the closure of the cavity depends upon its size. It may, however, close rapidly, as is shown by the following case:

Mr. F. W. M., age 58, was seen by me in a consultation, out of the city, Nov. 16, 1893. He was in the third day of an ordinary croupous pneumonia of the lower lobe of the right lung. I saw him again on the 24th, eight days later. Resolution was well established, the temperature had subsided to 99 degrees morning and 100.4 degrees evening. I learned later from his physician that his convalescence from the pneumonia was slow; two weeks after my last visit, Dec. 7, I was informed that he had a thrombo-phlebitis of the left leg and that he still had a slight cough, with no expectoration. His temperature with the phlebitis reached 102.3 degrees. His convalescence from the phlebitis was also slow. On the 29th of December he complained again of pain in the right side (not severe), began to cough and had a slight muco-purulent expectoration. I saw him in consultation on Jan. 6, 1894, seven weeks after the onset of his pneumonia. He was having night sweats, had a dry hacking cough and slight dyspnea. There was still some edema and tenderness in the leg and thigh. An examination of the right lung revealed a circumscribed area of dulness two inches in diameter, beginning just below the angle of the scapula. This area was sensitive on deep pressure; there was no edema of the wall. Respiratory sounds were absent and vocal fremitus diminished. The exploratory puncture gave one-half drachm of brown, sanguino-purulent, particularly offensive fluid.

Diagnosis.—Circumscribed gangrene not communicating with the bronchus. The question arose, was the phlebitis a sequence of the pneumonia and the gangrene the result of a

septic embolus from the vein, or was the gangrene the direct result of the pneumonia and the phlebitis one of the manifestations of sepsis? This is a question which I am unable to answer with any degree of certainty, but from the course of the disease I believe it was the result of a septic embolism.

Operation.—St. Joseph's Hospital, Chicago, January 9, an incision 2½ inches long was made in eighth interspace immediately below the angle of the scapula. As the pleura was approximated the tissues were edematous, showing that adhesions existed. (This tissue edema is one of the best evidences of adhesion of a suppurating focus to the wall either in the abdomen or chest; it far exceeds in value the vibration of the needle.) The pleura and underlying tissues were divided so as to admit the index finger; there was an escape of two ounces of fetid pus and some gas. Digital examination revealed a slough which was extracted with forceps; the cavity could be readily examined with the finger; its wall was irregular; there was no hemorrhage; it was not irrigated; a rubber drain was inserted; five days after the operation the odor had entirely disappeared and there was a clear serous discharge. On the twelfth day the drain was removed and on the thirty-third day he left the hospital with the wound entirely closed. This illustrates how early the drainage may be removed and how rapid the convalescence. Within three months he gained forty pounds and enjoys excellent health at the present time.

The extremity to which these patients may be reduced before an operation, and still be able to recover, is remarkable, as may be seen from the history of many cases; the surgeon should feel it his duty to operate on them even when it appears that they would not survive the hour of operation. The following is a good example:

Thos. K., age 22, on Sept. 9, 1897, was seized with a chill, severe pain in the left side and the usual symptoms of pneumonia. On the twelfth day of the pneumonia his temperature dropped and his symptoms improved. Four days later he began to cough and there was an expectoration of an offensive bloody fluid. A few days after the expectoration became yellow and still more offensive. The quantity increased with great rapidity, so that at the end of ten days the patient was expectorating a pint or more daily. He emaciated rapidly and became very weak. This deplorable condition continued until the 29th of December, when he was sent from the hospital to his home to die. Two weeks later he was seen by a very able practitioner who said he could not possibly survive three days. On the 2d of March I saw him in consultation; his pulse was 156, respiration 44, temperature 97 degrees; he was coughing incessantly; he could not speak above a whisper; the odor in the room from breath and expectoration was nauseating; he was emaciated to a skeleton, resting in a semi-sitting position from which he could not be moved; his pupils were dilated and he was apparently drowning from the accumulation of fluid. The nurse stated that this had been his condition for nine weeks. From this history obtained from the patient's friends and nurse, and the physical signs present, a diagnosis of gangrene of the left lung was made. Local anesthesia was employed and a three-inch incision was made in the eighth intercostal space, post-axillary line; about a quart of most offensive pus with necrotic shreds of lung escaped; a double drainage tube was inserted; he gave a few gasping respirations and I thought he was dying; the cough subsided in a few moments, his breathing became easier, and when I heard from him last, three weeks later, he was able to sit up in bed. The long period of time which had elapsed between the apparent hopelessness of his condition and the time of the operation is an illustration of how long these patients stand the deleterious effects of the pus accumulation and how they rally when relieved.

The complications that arise in operation for gangrene are pneumothorax and hemorrhage. In the former the lung should be harpooned or grasped by the forceps and sutured to the edge of the wound. Tuffier collected nine cases of hemorrhage with four deaths. The hemorrhage usually followed the removal of the tampon; the quantity of blood necessary to cause death under these conditions is very small compared with the fatal quantity from external hemorrhage. The greatest care should be exercised in the dressings, and irrigation should be avoided. Priestley Leech⁶⁴ of Halifax introduced iodoform into the cavity

⁶² Lancet, London, Oct. 20, 1888, p. 768.

⁶³ Lancet, London, Feb. 20, 1892, p. 440.

through the drainage tube with good effect. Tier,⁶⁵ Copenhagen, in four cases operated had three fatalities; one death from hemorrhage from drain pressure; in the successful case one-half of the lung was gangrenous, still patient recovered. Seitz⁶⁶ collected nineteen cases of gangrene operated, with four recoveries, four improvements and eleven deaths. Perier⁶⁷ reports continuous pleuro-pneumonic suture and drainage in second interspace for gangrene; the suture was made after opening the lung; recovery.

I have collected 96 cases of gangrene of the lung operated upon: 53 completely recovered; 3 recovered with fistula; 3 termination unknown; 37 died, 1 from cerebral embolism, 1 from meningo-encephalitis, 1 from pneumonia, 17 from undetermined causes, 3 from diffuse gangrene, 2 from septicemia, 4 from pyemia, 4 from exhaustion, 4 from hemoptysis.

Gangrene, from 1879 to 1897: Years According to Rotation.

Case 1, 1879. Cagley and Lawson, Brit. M. J., 1879, Vol. 1, p. 550. Male, 40 years. Gangrene, general condition grave; five weeks duration; pneumonia of left base posteriorly. Signs of cavity; adhesions. Exploratory puncture positive. Incision in ninth interspace, 3 oz. fetid pus, drainage. Death six days later. Necropsy: complete pleural adhesions, cavity with irregular walls, granular kidney, tuberculosis of right apex.

Case 2, 1880. Salomon Smith, Lancet, 1880, Vol. 2, p. 86. Male, 60 years. Gangrene. Duration, two months. Acute pneumonia, spurious, right base posteriorly. Signs of cavity. Exploratory puncture, putrid gas. Pneumotomy at the level of lower angle of scapula, no rib resection, ligation excited coughing. Death eight days later.

Case 3, 1881. Bull. Nordiskt. Archiv., 1881, vol. 13, p. 27, No. 17, in Runenberg Deutsche Archiv. für Klin. Med., 1881, p. 91. Female, 23 years. Gangrene. Duration two months. Acute broncho-pneumonia, left apex anteriorly. Signs of cavity. Puncture with a Pravaz syringe shows sero-sanguinous fluid. Incision two inches long in fourth interspace at level of the puncture, dilatation with forceps; some days later extraction of fragments of friable lung; carbolic irrigation. Recovery, several attacks of hemoptyses during following weeks.

Case 4, 1882. Leyden and Koch, 1882, quoted in Fabrickant. Male, 24 years. Gangrenous cavity in right lung, lower part; putrid bronchitis. Resection of sixth rib with thermo-cautery, drainage. Improvement.

Case 5, 1882. Leyden and Koch, 1882, quoted in Fabrickant. Female, 20 years. Gangrenous cavity in right lung. Opened by thermo-cautery, washed out with thymol sol., drainage. Died from septicemia. Necropsy: suppurative near portal vein, broncho-pneumonia of opposite side.

Case 6, 1883. Boechen, Cent. für Chir., 1883, No. 37, p. 598, and Med. and Raccogliatore, 1891, Vol. 2, p. 561, 5th series. Female, 27 years. Gangrenous abscess of lung; pneumonia; right apex laterally; adhesions. Exploratory puncture positive. Incision in right interspace without rib resection; puncture, then pneumotomy; issue of pus and of pulmonary debris. Amelioration; case reported before complete recovery.

Case 7, 1883. Sutton in Mosler, Wiesbaden, 1883, p. 38, and in Ramsay, Obs. 2. Male, 34 years. Gangrene, large cavity; Pneumonia five years previously; left base. Signs of cavity. Exploratory puncture, issue of pus. Incision in sixth interspace, drainage daily, carbolic irrigation. Sudden death thirty-first day. Necropsy: large cavity of the base.

Case 8, 1884. Cagley and Gould, Brit. Med. Jour., Jan. 1884, Vol. 1, p. 1045. Female 12 years. Acute metastatic gangrene. Duration eight days. Pyemia following otitis with an old mastoiditis; left base posteriorly. Signs of cavity. Puncture with large trocar, issue of pus and debris. Recovery in forty days.

Case 9, 1884. Drinkwater, Trans. of the Northumberland and Durham Society, May 15, 1884, in Revue des Sc. Méd., 1885, Vol. 25, p. 300. Male, 60 years. Acute gangrene. One month duration. Chronic bronchitis, acute pneumonia; right apex; adhesions. Incision of an abscess just below the clavicle, drainage of a pulmonary cavity through intercostal space. Improvement, recurrence three months later, incision and resection of one and one-half inches of the third rib, ablation of a portion of the gangrenous lung, drainage and irrigation; recovery without fistula.

Case 10, 1884. Fenger, Med. News, June 7, 1884, in Cent. f. Chirurg., 95, p. 208. Male, 36 years. Circumscribed gangrene. Six weeks duration. Croupous pneumonia; right base anteriorly. Signs of cavity. Puncture with hypodermic issue of gangrenous fluid. Resection of the fifth rib, puncture of the cavity and incision with the cautery, saline irrigation gave rise to cough, drainage. Rapid improvement, drain removed on twenty-second day; fistula six weeks after operation; recovery.

Case 11, 1884. Ferney, Dublin Jour. of Med. Sciences, Jan. 19, 1884, in Revue des Sc., 1885, Vol. 25, p. 299. Male, 30 years. Gangrenous cavity and empyema; base posteriorly. Incision at the level of lower angle of the scapula. Death five days later. Necropsy: diffuse gangrene.

Case 12, 1885. Gairchier and McLeod, quoted by Fabrickant, 1885. Boy. Gangrenous cavity; left lung. Resection of ribs, drainage. Death after few days.

Case 13, 1886. Brookhouse, Lancet, 1886, Vol. 1, p. 1111. Male, 36 years. Gangrenous abscess, three months duration. Spurious pneumonia; left base posteriorly. Signs of cavity; adhesions. Puncture with large trocar in eighth interspace, axillary line, daily irrigation, cough. Death seven days later.

Case 14, 1886. Hevilich, Charité Annal, 1886, Vol. 2, p. 230. Female, 27 years. Pulmonary abscess, expectoration purulent and fetid. Three weeks duration. Puerperal infection; right base posteriorly. Signs of cavity; adhesions. Puncture positive, several punctures at the level of lower border of ninth rib, without result; positive puncture in ninth interspace in axillary line. Resection of four cm. of ninth rib; puncture, 3 cc. of pus and fetid clots, dilatation of the tract, we came upon the cavity the size of a fist with irregular walls. Hemorrhage into cavity during operation arrested by tamponade; death three days later. Necropsy: Puerperal

metro-peritonitis and para-metritis, right pneumonia and cavity of base of right lung the size of goose egg, embolism of the pulmonary artery, firm adhesions, another focus of pulmonary necrosis superficially in the right face.

Case 15, 1886. Perier, and de Bourin, in Francis Médicale, 1886, Vol. 2, p. 1463. Female, 12 years. Gangrene, hemoptysis and cavity, and bacilli. Several years duration. The pulmonary affection not determined; right antero-lateral region. Resection of 5 cm. of fifth and sixth ribs, pneumotomy with the cautery at depth of 3 cm., drainage, no irrigation. Complete recovery, no details.

Case 16, 1886. Wagner, Berlin Clin. Woch., Sept. 6, 1886. Male, 17 years. Gangrene of the lung and putrid pleurisy; croupous pneumonia of left side. Incision in eighth space near vertebral column, offensive odor, piece of gangrenous lung discharged through wound. Gradual recovery.

Case 17, 1887. Zelas, Corresp. Blatt of Schweizer, Aerzte, 1887, Vol. 17, p. 455. Male. Pyemic abscess. Five and one-half months duration. Pyemia secondary to a foreign body in the larynx; right base posteriorly. Signs of cavity; insufficient adhesions. Incision and resection of seventh rib (6 cm.), opening of cavity at a depth of 3 cm., tamponade and drainage. Death fourteen days later. Necropsy: Pyo-pneumothorax, insufficient adhesions, central edema from thrombosis of the jugulars, abscesses in the two lungs.

Case 18, 1887. Runenberg, Deutsche Aschit. für Med., 1887, Vol. 41, p. 91, Obs. 2. Female, 23 years. Gangrene and circumscribed pneumothorax; chronic bronchitis and multiple bronchiectasis bilateral; left upper lobe anteriorly and posteriorly. Signs of cavity; total adhesions. Exploratory puncture without result, puncture in the axillary line to the fourth interspace positive. Resection of 4 cm. of fourth rib in post-axillary line, small cavities, no pus, punctures with a fine trocar, no cavity. Two days later issue of pus through the tract; death ten days later. Necropsy: communication of the pelvis with the wound, gangrenous cavity of lower lobe; cavity of the upper lobe of 4 cm. into which a bronchus opens, numerous small cavities in the upper and lower lobes, no more in the left lung, small cavities in the right at the base.

Case 19, 1887. Leyden, Arch. Gen. de Méd., 1887, Series 7, Vol. 20, p. 472. Gangrene; puncture. Incision, escape of large quantity of pus, irrigation. Recovery.

Case 20, 1887. Guernonpuz, Académie de Médecine, 1887, Vol. 18, p. 332. Male, 23 years. Gangrene. Four years duration. Typhoid fever; base. Signs of cavity. Exploratory pneumotomy; resection of two ribs, two pneumotomies. Recovery.

Case 21, 1887. Godlee, Lancet, 1887, Vol. 1, p. 512. Female, 19 years. Gangrenous abscess. Fourteen days duration. Pneumonia of six weeks duration; left base. No signs of cavity; adhesions; exploratory puncture. Incision in the eighth interspace without rib resection, cavity at a depth of 6 cm., drainage. Recovery, three and a half months later slight scoliosis.

Case 22, 1887. Godlee, Lancet, 1887, Vol. 1, p. 513. Female, 44 years. Gangrenous abscess; eight days duration. Pleuro-pneumonia of twenty-four days duration; right base anteriorly. No signs of cavity; adhesions. Incision in the seventh interspace above the nipple, no rib resection, drainage. Recovery, six weeks after opening of an abscess into the colon (Quincke) necessitated between a gangrene or an empyema.

Case 23, 1887. Dubmeil, Gaz. Hebd. des Sc. Méd. de Montpellier, 1887, p. 517. Female, 25 years. Chronic gangrene; duration four months. Broncho-pneumonia, hemoptyses, no tubercle bacilli; right base posteriorly. Signs of cavity; adhesions. Puncture with fine trocar for the diagnosis of adhesions. Incision, resection of one and one-half cm. of the sixth rib; pneumotomy; opening of a series of cavities of the size of a hazel nut, drainage, boracic acid irrigations incite cough and suffocation. Death one month later without improvement.

Case 24, 1888. Koch, in Openschowski Wratsch., 1888, p. 713, in Zeit. für Klin. Med., 1889, Vol. 16, p. 303. Male, 30 years. Gangrenous abscess; four months duration; pneumonia four months previously; right base between the post-axillary and mammary lines. Signs of cavity; adhesions. Two exploratory punctures negative, one month and three weeks before the pneumotomy. Resection of fifth and sixth ribs (10 cm.), opening of a cavity at a depth of 2 or 3 cm. the size of a fist, gangrenous focus in an old abscess, cauterization with the thermo-cautery. Recovery, irrigation with permanganate of potash excites cough, drains removed thirty-six days after the operation; eighteen months after recovery slight scoliosis and scar, depressed respiration, feeble on the operated side.

Case 25, 1888. O'Keel, Lancet, 1888, Vol. 1, p. 622. Pulmonary gangrene; several weeks duration; pleuro-pneumonia; right base; adhesions. Pneumotomy. Recovery.

Case 26, 1888. Pollard, in Pasteur Chir. Soc. of London, 1888, in British Med. Jour., 1888, Vol. 2, p. 279. Male, 7 years. Gangrene. Three weeks duration. Pneumonia, probably secondary to a foreign body; right apex anteriorly. Signs of cavity. Incision in the second interspace, enormous cavity; counter-opening in sixth interspace. Death on thirteenth day. Necropsy: Cavity occupying one-third of the center of lung (the three lobes affected), esophagus adherent to the right bronchus and communicating with the same, cause of this communication unknown.

Case 27, 1888. Page, London Lancet, 1888, Vol. 1, p. 572. Male, 13 years. Pulmonary gangrene with hydropyco-pneumothorax; run over by a car. Signs of cavity, probably due to pneumothorax. Aspiration, 20 ounces of sanguinous serum. Pleura opened and tube inserted in fifth left interspace in mid-axillary line, offensive pus evacuated, tube taken out about one month after operation; immediate improvement; discharge lessened daily, piece of pleura and lung discharged, complete recovery.

Case 28, 1888. Pasteur, Brit. Med. Jour., 1888, Vol. 2, p. 879. Male, 7 years. Gangrene of lung; four weeks duration; insidious onset but had developed rapidly; right upper lobe. Signs of cavity. Cavity incised out extreme of right second space one inch from sternum, large quantities of gangrenous lung and putrid fluid were expelled, cavity reached to sixth rib, opening made in sixth space, and drainage tube inserted, cavity washed out twice daily, pus appeared later. Next morning patient much relieved; expectoration small quantities of frothy spits, free from pain; improvement not maintained; after ten days fetor and temperature reappeared; patient sank rapidly three days later. Necropsy: Huge cavity occupied anterior one-third of lung (right) lined with thin layers of granulation tissue, pericarditis present, esophagus adherent to bronchus, commenced between esophagus and right bronchus.

Case 29, 1888. Seitz, Inaug. Dissert., Würzburg, 1888. Male, 35 years. Acute gangrene; five weeks duration; typhoid fever six weeks; left base posteriorly. Signs of cavity; adhesions. Resection of seventh and eighth ribs, 4 cm., incision of lung with bistoury, cauterization, drainage. Death twelve days after a second cavity containing 250 grams was discovered. Necropsy: A right pneumonia and catheter.

Case 30, 1888. Shewen, Aust. Med. Gaz., Sydney, 1888-89, Vol. 8, p. 173. Gangrene; pneumotomy. Recovery.

Case 31, 1889. Bastanelli, Bull. de Soc. Lanc. de Osp. Roma, 1889-90, Vol. 10, p. 35. Female, 34 years. Acute gangrene; duration one month. Septicemia following ovariotomy; right base axillary line. Resection of fifth and sixth ribs in axillary line, puncture cavity 1½ cm. deep, irrigation of cavity, syncope, tamponade. Death fourteen hours later, coma

⁶⁴ Lancet, Jan., 1894, p. 87.

left hemiplegia. Necropsy: Embolism of sylvain artery, thrombosis of a pulmonary vein.

Case 32, 1889. Freiberg, Meditzina, St. Petersburg, 1889, Vol. 1, No. 50, in Chlucnerkink, 1894, p. 763. Observation 41. Male, 26 years. Fetid abscess with hemoptyses; two months duration. Acute frank pneumonia; left base posteriorly. Signs of cavity; doubtful adhesions. Incision internal to the lower angle of the scapula; resection of the sixth rib, pelvis thickened where there has been applied a paste; enlargement of the opening with the cautery, cavity 3 cm. deep, into which the bronchi opened, drainage and iodoform gauze. Death sixteen days later, septicemia. Necropsy: Purulent and hemorrhagic pleurisy, septic lobar pneumonia, multiple adhesions, the cavity the size of a fist.

Case 33, 1889. Ramsay, Annals of Surg., 1889, Vol. 2, p. 144, and 1890, Obs. 2. Male, 25 years. Gangrenous abscess; four weeks duration. Injury by forearm of thorax and lungs; axillary region and anteriorly. Signs of cavity; adhesions. Thoracotomy, resection of the second, third, fourth, fifth, sixth and seventh ribs, pneumotomy, issue of pus and of debris of garments. Recovery.

Case 34, 1889. Smith, S. C., Lancet, 1889, Vol. 2, p. 113. Female, 39 years. Gangrenous abscess; duration five weeks. Pneumonia for three weeks; right base posteriorly. Signs of cavity; adhesions. Exploratory puncture at the angle of scapula without result. Incision without rib resection at lower angle of scapula, dilatation of a focus opening of a small cavity. Recovery with fistula in four weeks.

Case 35, 1889. Von Oppenshouski, Zeitschrift für Klin. Med., Berlin, 1889, xvi, 393 and 398; Male, 30 years. Lung abscess and gangrene, three weeks after onset coughed up cup of fetid pus, no tubercle bacilli; four months duration. Exposure and cold; right side middle lobe. Signs of cavity; pleural adhesions. Negative puncture on right side, repeated punctures a week later give negative results. Incision between mammillary and hind axillary line over fifth and sixth ribs were excised to extent of 10 cm.; opened directly into lung with thermo-cautery, at depth of 2 or 3 cm. cavity was opened, patient coughed and emptied out of wound a greenish, fetid pus; lining of cavity suspended with fingers, cavity irrigated with dilute potassium permanganate sol., drainage and antiseptic packing, wound irrigated twice daily at first and daily later. Recovery; patient discharged as cured seven months after admittance.

Case 36, 1889. Walsham (Symonds), St. Bartholomew Hosp. Reports, 1889, Vol. 25, p. 253. Male, 33 years. Acute gangrene; seven weeks duration. Pneumonia, aspiration of material (submission); left base posteriorly. Rib resection, drainage and irrigation. Improvement; death five weeks after, hemoptysis from the pressure of the drain. Necropsy: Cavity diminished in size.

Case 37, 1890. Anderson, Am. Pract. and News, Louisville, 1890, Vol. 10, p. 10. Male, 32 years. Gangrene cavity; forty-five days duration. Pneumonia; lower lobe. Puncture in sixth interspace, one inch behind axillary line, pus. Incision two inches long over seventh interspace, one inch behind axillary line, down to intercostal muscles; inserted trocar five inches long, blood; inserted needle and obtained pus; reinstated trocar into cavity and drew off one pint pleurant matter; dilated opening with forceps, introduced rubber tube, irrigated next day, some fluid passing into trachea. Recovery; cough ceased.

Case 38, 1890. Ramsay, Annals of Surg., 1890, Vol. 2, p. 34. Male, 32 years. Gangrene. Acute pneumonia; right base posteriorly. Signs of cavity; adhesions. Exploratory puncture positive. Incision and resection of 3 cm. of seventh rib, puncture incision above the trocar with the bistoury and forceps, issue of gangrenous liquid, drainage. Recovery in six months, the drain removed the seventh day but was replaced on account of retention, no fistula.

Case 39, 1891. Fenger and Hollister, Münch. Med. Woch., 1891, p. 8. Male, 34 years. Gangrenous abscess. Suppurating hydatid cyst; lower lobe. Signs of cavity. Exploratory puncture. Incision of the third interspace anteriorly, counter-opening in fifth interspace in axillary line. Recovery in six weeks.

Case 40, 1891. Krecke, Münch. Med. Woch., 1891, Vol. 38, p. 399. Male, 20 years. Gangrene of lung, purulent pleurisy. Stricture of esophagus from alkali poisoning, unable to pass tongue; right side empyema and gangrene lower lobe. Esophagotomy, external resection of ribs for empyema; gangrenous area was opened, cavity discovered the size of a chicken's egg. Patient died six hours later.

Case 41, 1891. Krecke, München Med. Woch., 1891, p. 399. Female, 15 years. Gangrene. Stricture of the esophagus, treatment by esophagotomy; right base posteriorly. Pneumotomy. Death from exhaustion. Necropsy: Multiple abscesses in the left lung, the right cavity cicatrizing.

Case 42, 1891. Porter, Journal of Am. Med. Ass'n., 1891, Vol. 16, p. 335. Young female. Gangrenous abscess. Grippe after confinement; left base. Signs of cavity; adhesions. Incision and rib resection, irrigation, drainage. Complete recovery.

Case 43, 1891. Ochler, München Med. Woch., 1891, p. 713. Male, 30 years. Chronic gangrenous abscess; two years and seven months. Pleuro-pneumonia two years previously, expectorate gangrenous and hemoptoic; left base posteriorly. No signs of cavity except for one month; no adhesions. Resection of the seventh rib, pneumothorax; the operation abandoned; drainage of the pleura, pneumothorax absorbed within a few days; four weeks later a new incision at the same point and depth of 5 cm. in the lung; the cavity opened spontaneously into the liver, two days later drainage. Recovery, purulent fistula one and a half years later; the patient has been troubled since his fistula closed (fetid sputum fever).

Case 44, 1891. Porter, Journal Am. Med. Ass'n., 1891, Vol. 16, p. 335. Male, middle-aged. Gangrenous abscess; left base. Signs of cavity, abscess contains gas; adhesions. Incision and rib resection, irrigation, drainage. Complete recovery.

Case 45, 1891. Thue, Nordiski-Magaz., 1891, p. 771, in Johnesbericht, 1891, Vol. 11, p. 445. Male, 37 years. Gangrene. Acute bronchitis and double pleurisy; right apex; partial adhesions, insufficient. Resection of the third and fourth ribs, lungs fixed in the incision by sutures because of the insufficiency of the adhesions. Purulent pleurisy, death three and a half months later. Necropsy: Purulent pericarditis.

Case 46, 1892. De Cerenville and Roux, Rev. Méd. de la Suisse, Romande, 1892, p. 233. Male, 53 years. Acute gangrene; four weeks duration. Bronchiectasis; left base anteriorly and in axillary line, disseminated foci. Signs of cavity. Pneumotomy in extremis, resection of fifth rib, axillary line opening with a cautery, a large cavity. Death a few hours later. Necropsy: Bilateral bronchial dilatations, gangrenous cavity of left base.

Case 47, 1892. De Cerenville and Roux, Rev. Méd. de la Suisse, Romande, 1892, p. 229. Male, 18 years. Acute gangrene; eight weeks duration. Grippe in 1889; bronchitis; right base posteriorly. Signs of cavity; partial adhesions. Puncture, serous fluid. Resection of 6 cm. of ninth rib, partial pneumothorax, lung grasped with forceps, immediate suture of two pleurae; purulent pleurisy eight days later; puncture, pus; pleurotomy sixteen days later complete pneumothorax, second pleurotomy. Recovery; seen nine months later, cured with excavation.

Case 48, 1892. De Jersey, W. B., Lancet, Vol. 1, 1892, p. 21. Child 21 months.

Gangrene of lung; six weeks duration. Pneumonia, history phthisis; left side. No signs of cavity positive; pleural adhesions. Puncture in left chest rib, sixth space, axillary line, and in same space to angle of scapula, pus was withdrawn. Incision in sixth space between post and mid-axillary lines, one dram of pus of fetid odor escaped; temperature fell after operation. Death three days after operation. Necropsy: Left lung solid, tubes thick and containing pus, scattered particles of gangrene; bronchitis.

Case 49, 1892. De Bourman, same, Female, 12 years. Gangrene. Broncho-pneumonia or suppurative interlobar pleurisy; middle lobe of right lung. Signs of cavity. Resection of fifth and sixth ribs, incision with thermo-cautery through 3 cm. of lung tissue, large drain, irrigation. Recovery.

Case 50, 1892. Delagrue, Cong. Trans. de Chir., 6, 1892, p. 583. Male, 37 years. Gangrene of lung; ten months duration. Fall upon chest; base of left lung. Trocar finds pus, puncture at level of ninth rib. Resection of seventh, eighth and ninth ribs in their entirety from posterior angle, opening of abscess, escape of one-half liter of greenish, fetid pus, irrigation of cavity with 1 oz. Cl. 1 to 2000, drainage. Recovery; drainage tube removed twenty-seven days after recovery; fistula.

Case 51, 1892. Hagen, Thomwrat, 1891, and Meditzina, St. Petersburg, 1892, Vol. 4, p. 455. Male, 32 years. Gangrenous abscess. Fibrinous pneumonia; right base anteriorly. No signs of cavity; adhesions. Exploratory puncture, fetid pus. Incision of 5 cm. in the fourth interspace. Recovery in one month.

Case 52, 1892. Monod, Soc. de Chirurgie, 1892, p. 578, and 1895, p. 733. Male, 48 years. Acute gangrene; twenty days duration. Pneumonia, two months duration; left base posteriorly. Signs of cavity; adhesions (not diagnosed). Exploratory puncture in ninth interspace negative, puncture in eighth interspace positive. Pneumotomy without rib resection at the level of eighth interspace, abscess situated at depth of 10 cm. Recovery in one and a half months.

Case 53, 1892. Perier and C. Paul, Bull. Acad. de Méd., 1892, Vol. 27, p. 375. Male, 58 years. Gangrene; four months duration. Bronchitis and gangrenous septicemia seven months previously; left apex. Signs of cavity; loose adhesions. Incision in the second interspace, focus and depth of 2 cm., containing 60 c.c. of pus, drainage (naphthol camphor). Recovery in fifty days.

Case 54, 1893. White, Medical News, 1893, Vol. 62 p. 38. Female, 30 years. Chronic gangrene (first focus), second focus three and a half months since; three and a half months duration. Old infectious pneumonia, acute pleuro-pneumonia; right base anteriorly and posteriorly. Signs of cavity; adhesions. Exploratory puncture positive. Incision in sixth interspace, two ounces of fetid pus, irrigation, drainage; incision of rent in post-axillary line sixth interspace, issue of several ounces of fetid pus and fragments of gangrenous lung. Cured, two months drain removed, cured in eight months; observed two years after, cured.

Case 54, 1893. Hofmaki, Wiener Klin. Woch., 1893. Male, 25 years. Gangrenous abscess, putrid bronchitis; one month duration. Bronchitis; left apex anteriorly. Signs of cavity; adhesions. Incision in the second interspace, cavity not opened; six days later resection of 8 cm. of third rib; puncture of lung, at third puncture issue of air and secretion upon dilatation of tract; hemorrhage arrested by tampon. Recovery in one and a half months without fistula.

Case 55, 1893. Tizebicky, Wiener Med. Woch., 1893, Nos. 21 and 22. Male, 58 years. Chronic gangrenous abscess; three months duration. Traumatic pneumonia three months previously; right base anteriorly. Signs of cavity; adhesions. Exploratory puncture. Resection of the fourth rib (4 cm.); two days after the puncture opening of a gangrenous cavity. Death sixteen hours later.

Case 56, 1894. Grube, in the Clin. Viestnik, 1894, p. 63, observation not published. Male, 42 years. Gangrenous abscess, no bacilli of tuberculosis; two years duration. Fibrinous pneumonia; right upper lobe anteriorly, thorax retraction. Signs of cavity; adhesions. Incision in second interspace; exploratory puncture with hypodermic needle, issue of pus; incision of parenchyma with cautery to depth of 6 cm., small, insignificant cavity; five days later the larger cavity opened spontaneously through the incision, no drainage, strand of gauze. Recovery; he left hospital one and a half months later with a wound on its way to cicatrization.

Case 57, 1894. Habershou, Lancet, 1894, Vol. 1, p. 1012. Male, 32 years. Gangrene of lung; six months duration. Syphilis; left apex and right base, advanced toward bases. Signs of cavity; pleural adhesions. Positive puncture. Portion of rib resected, but little pus obtained. Patient died a short time after operation. Necropsy: Right lung firmly adherent posteriorly, pleura thickened, extreme apex fairly healthy, though emphysematous; posterior two-thirds of lung a series of red eating cavities; in left lung broncho-pneumonia, gangrenous patch; tubercle bacilli found, also giant cells.

Case 58, 1894. Priestly, Teck, Lancet, Vol. 1, p. 87. Male, 22 years. Chronic abscess complicated with secondary gangrene; four months duration. Pleuro-pneumonia, six months duration; left side anteriorly. No signs of cavity; adhesions. Incision in third interspace; multiple punctures (5), negative puncture in second interspace, the second puncture brought pus; incision with the trocar; dilatation with the forceps of Lister, pus, drainage. Recovery after having hemoptyses twice during convalescence; complete recovery six months after.

Case 59, 1894. Mackay, Inter Col. of J. F. M. and S., Melbourne, 1894, Vol. 1, p. 52. Male, 12 years. Gangrenous abscess, hemoptysis; Several days. Acute pulmonary affection of five weeks duration; no diagnosis; right base antero-laterally. No signs of cavity; adhesions. Puncture negative. Incision below the lower border of the scapula; resection of two ribs, adhesions; multiple punctures in all directions, at last upon finding a small cavity the size of a walnut containing gangrenous debris, this cavity was incised. Death, hemoptysis. Partial Necropsy (lung only): The upper lobe normal, the lower and middle lobes adherent; a cavity, the size of an orange opened, separated by thicknesses of 3 mm.; five or six other small abscesses of lower lobe, abscess of the middle lobe.

Case 60, 1894. Rodman, Am. Prac., Louisville, May 5, 1894, in Chir. Am., 1895. Young male. Acute gangrene. Infectious pneumonia following a fracture of the ribs. Incision and resection of sixth rib twenty days after the accident (four inches), pus and pulmonary debris; repeated tamponade. Recovery.

Case 61, 1894. Roebert, no date, given immediately under another dated May, 1894. Local gangrene. Resection. Recovery.

Case 66, 1894. Roebert, Inaug. Dissert., Kiel, 1894. Male, 28 years. Gangrenous abscess, gangrenous pneumonia; three weeks. Old bronchial dilatations; third interspace anteriorly, right base posteriorly. Signs of cavity; no pleural adhesions. One puncture in the ninth interspace negative, one puncture in the third interspace anteriorly positive. Application of a paste of chlorid of zinc; resection of 3½ cm. of the third rib; spontaneous opening of the cavity ten days later; ten weeks later the same operation posteriorly at level of fifth rib, opening of cavity on seventh day. Death two days after opening second cavity. Necropsy: Old bronchial dilatation, broncho-pneumonia cachexia; the patient improved after first operation, failed after second.

Case 62, 1895. Bazy, Soc. de Chirurgie, 1895, p. 69. Male, 20 years. Gangrene; right base; partial adhesions. Incision 10 cm. long parallel to the ninth rib, which is resected as well as the eighth (6 cm.); digital exploration through a small opening in pleura, adhesions above the incision, second incision above the first; pleural adherent gangrenous focus, 12 cm. deep. Cured in twenty days. Death three or four months later from epilepsy.

Case 63, 1895. Harrison, in Quincke Mittheil. Aus. den Greng., 1895, Vol. 1, p. 1011, table 1b, observation 1. Female, 27 years. Gangrenous abscess; six days duration. Pulmonary embolism following puerperal fever of three weeks standing; right base posteriorly. No signs of cavity; adhesions. Exploratory puncture. Resection of four cm. of the ninth rib, opening of the cavity containing 300 c.c. of pus. Death three days later. Necropsy: Pyemia.

Case 64, 1895. Krause, Berliner Klin. Woch., 1895, p. 347. Male, 36 years. Chronic gangrene; nine months duration. Infectious pneumonia; left base posteriorly; no adhesions. Resection of 12 cm. of ninth and tenth ribs, opening of the pleura; the upper lobe retracted, the lower lobe adherent to the thorax, tamponade with iodoform gauze; five days later sufficient adhesions except at one point (above); opening of the cavity, cavity the size of an apple, gangrenous fragments of lung, two drains. Recovery; the bronchial fistula closed twenty-five days later; three and a half months later cured a little roughness of respiration, and amplitude of thorax slightly diminished.

Case 65, 1895. Krause, Berliner Klin. Woch., 1895, p. 347. Male, aged 33 years. Purulent pleurisy; gangrenous abscess (?); three months' duration. Bronchitis and right side pleurisy; right base anteriorly; adhesions. Resection of fourth and fifth ribs in the maxillary line; pulmonary fistula; pneumotomy; at 2 cm. we come upon a cavity the size of an egg; tamponade. Recovery; left the hospital three weeks after the operation, wound healing.

Case 67, 1895. Podieze, Rev. Gende Chir. et de Ther. Jour. des Praticiens Paris, Nov. 19, 1895. Gangrene of left lung. Incision 12 cm. long from above down in left subclavicular region; excised 3 cm. of second and third ribs; sutured pleural transverse incision in lung; fetid pus escaped; walls of cavity swelled; irrigation with Thiersch sol.; iodoform tampon. After third dressing pus lost fetor. Wound healed in three weeks. In forty-five days after operation patient had gained thirty-one pounds.

Case 68, 1895. Quincke, Mittheilungen aus der Grezgebden Medici und Chir., 1895, Bd. 1, H. T. 1, obs. 6, p. 25, and Tab. 2, observation, 8, pp. 30-31. Male, aged 34 years. Chronic purulent abscess; duration one and one-half years; pneumonia complicating grip; left base and the axillary line; signs of cavity; adhesions. Resection of the third rib in the axillary line anteriorly; opening of cavity. Death one and one-half hours later. Necropsy: Several cavities if only opened; death from exhaustion; recent gangrene in right; pleural exudate in the right.

Case 69, 1895. Quincke, *ibid.*, Bd. 1, H. T. 1, Tab. 1, observation 6, pp. 10 and 11, and obs. 1, p. 8. Male, aged 33 years. Acute gangrene (gangrenous abscess); duration four weeks; acute pneumonia (two and one-half years; right base posteriorly; signs of cavity; adhesions. Exploratory puncture; issue of pus. Resection of eighth, ninth and tenth ribs (6 cm. in the scapula line); H-shaped incision at level of ninth rib; two sutures of lung to the pleura; multiple exploratory punctures without result; three days later a purulent fistula formed; opening enlarged with the cautery; five days later rib resection; drainage. Recovery in six weeks; completely cured in two months.

Case 70, 1895. Quincke, *ibid.*, 1895, Bd. 1, H. T. 1, obs. 5, p. 23 and Tab. 2, pp. 28-29. Male, aged 39 years. Chronic gangrenous abscess with secondary bronchiectasis; duration ten months; left base posteriorly; signs of cavity; partial adhesions ascertained by the puncture. Exploratory puncture in fifth interspace, axillary line; pus, sero-gangrenous fluid. Application of paste of chlorid of zinc; resection of 3 cm. of sixth rib fourteen days later; puncture; pus; opening of the cavity with cautery. Death three days later. Necropsy: Sero-purulent pleurisy; encysted in the left; multiple cavities; chronic meningitis.

Case 71, 1895. Tuffier, Soc. de Chir., 1895, p. 769, obs. 1. Male, aged 59 years. Acute gangrene, fifteen days duration. Infectious pleuro-pneumonia of forty-five days' duration; right base in axillary line; signs of cavity; no adhesions. Incision in sixth interspace without rib resection; complete pneumothorax; total retraction of the lung; impossible to open the lung; drainage of the pleura. Recovery.

Case 72, 1895. Tuffier, *ibid.*, 1895, p. 767, obs. 5. Female, aged 19 years. Gangrene of three months' duration. Acute pneumonia and pyemia since three and one-half months; right apex anteriorly; signs of cavity; partial adhesions. Incision at level of third interspace; no adhesions at this point; separation of the parietal pleura adhesions at the level of second rib; resection of 5 cm. of this rib; pneumotomy; opening of a cavity the size of head of fetus; tamponade. Death fifteen days later; meningococcal meningitis. No necropsy at the time of operation; the patient presented the accidents of gangrenous embolism of the sylvian artery; this suddenly the same day as the pneumotomy and as the trephining of the head.

Case 73, 1895. Tuffier, *ibid.*, 1895, pp. 776 and 789, obs. 4. Male, aged 60 years. Acute gangrene of six weeks duration. Pneumonia; right base posteriorly; no signs of cavity; partial adhesions. Incision in eighth interspace; separation of the parietal pleura adhesions at level of the seventh rib; resection of seventh rib; opening of a cavity the size of a fetus head; tamponade. Death six days later; cause, hemoptysis. Necropsy: Hemorrhage in the center of the cavity; no pleurisy or pneumothorax.

Case 74, 1895. Tuffier, *ibid.*, 1895, p. 771, obs. 5. Male, aged 41 years. Acute gangrene of three weeks duration. Pneumonia of four months; right base anteriorly; signs of cavity; adhesions. Incision below the fourth rib within the nipple; no rib resection. Death five days later; hemoptysis. No necropsy.

Case 76, 1896. Duret, Arch. de Medicine, 1896, Vol. 1, p. 67. Female, aged 21 years. Chronic gangrene of the lung. Old bronchiectasis; right base posteriorly; signs of cavity; positive puncture. Rib resection (three ribs), 7 to 8 cm.; incision of the pleura; pneumotomy; opening of a cavity the size of a hen's egg, into which opened two bronchi; cauterization; drainage. Amelioration; recurrence nine months later; eunetteage of the cavity; counter-opening; drainage; fistula resulted, which was operated on with success four years later. Complete recovery two and one half years after last operation.

Case 78, 1896. Meakin, Brit. Med. Jour., 1896, H. p. 716. Female, aged 31 years. Probable gangrene of pleura and lung of a few days' duration. Acute pneumonia; adhesions. Sixth and seventh ribs resected in anterior axillary line, one-half inch from each; pleural cavity opened; grayish-black very fetid fluid escaped from lung; did not collapse; lung was hard, except one spot, which was doughy; in this spot a forepaw was plunged, followed by a drainage. Distress diminished steadily; recovery after first few hours; discharge dark red, tarry quality, becoming like pus; discharge after first four days was not fetid.

Case 79, 1896. Phillips and Nash, Lancet, 1896, Vol. 2, p. 1454. Male, aged 36 years. Acute gangrene of one month. Pleuro-pneumonia; right base in axillary line; no signs of cavity; adhesions. Exploratory puncture; pus, blood, debris. Incision in the sixth interspace; resection of

one and one-half inches of sixth rib; gangrenous cavity; debris of neurotic lung; irrigation; no improvement; one month later resection of seventh and eighth ribs, two inches (posterior axillary line); numerous exploratory punctures without result; no cavity. Recovery fourteen months; purulent discharge through the wound at several relapses; drain one year; hemoptysis thirteen months after the operation. Complete recovery; seen four years later.

Case 80, 1896. Smith and Treve, Lancet, 1896, Vol. 2, p. 532. Male, aged 40 years. Gangrenous abscess of one and one-half months. Acute pneumonia; between inner border of scapula and spine; no signs of cavity; adhesions. Negative exploratory puncture two days before operation. Incision and resection of rib; opening of a small abscess. Recovery, but later relapse and formation of a second abscess at the site of the first, which is opened and drained.

Case 81, 1896. Smith and Treves, *ibid.*, p. 522. Male, aged 45 years. Fetid gangrenous abscess of four months duration. Pleuro-pneumonia; posteriorly below the angle of the scapula; signs of cavity; partial adhesions. Incision and rib resection; exploratory puncture negative; cavity the size of a cricket ball; pleura not adherent at the base; protected with tampon. Death twelve days after a second cavity containing 250 grams was discovered. Necropsy: A right pneumonia and cachexia.

Case 82, 1897. Andrews in Morillon These de Paris, 1897, p. 71, observation 2. Male, aged 42 years. Gangrenous abscess of fourteen weeks' duration. Pneumonia; left base anteriorly and laterally; no signs of cavity; adhesions. Resection of 8 cm. of fifth rib in axillary line; puncture; pus 8 cm. deep; incision and eunetteage of cavity; during the operation syncope caused by an embolism of lung tissue. Improvement; the patient was lost sight of before recovery was complete.

Case 83, 1897. Andrews in Morillon These de Paris, 1897, p. 75, obs. 5. Male, aged 24 years. Gangrenous abscess of two years' duration. Pneumonia; left lower lobe; signs of cavity; adhesions. Resection of 2 cm. of two ribs in axillary line; incision of lung with the bistoury; cavity 4 cm. deep, contained necrotic lung tissue; iodoform dressing. Rapid recovery. Death two years later; cerebral syphilis probable cause.

Case 84, 1897. Bazy, Soc. de Chirurgie, 1897, p. 67. Gangrene; adhesions. Pneumotomy; extraction of 32 grams of shreds of pulmonary sloughs. Result unknown.

Case 86, 1897. Jagle et Raffray in Morillon th. Paris, 1897, p. 105, et Soc. Anst., 1893. Female, aged 41 years. Acute gangrenous abscess, putrid expectorate, thirteen days duration. Acute frank pneumonia six weeks before; right base posteriorly; signs of cavity; adhesions; two negative punctures. Incision in the eighth interspace (cocain anesthesia); puncture of the pleura negative; incision; a violent cough brings forth two to three spoonfuls of fetid pus; irrigation with sublimate provokes violent cough; issue through the wound; two pulmonary sloughs; two drains. Improvement for three days; death the fourth day. Necropsy: Cavity in the right lower lobe posteriorly, into which many bronchi open.

Case 87, 1897. Lapujko, Soc. de Med. des Kieff, Wratch, 1897, p. 173. Female. Gangrene; pneumotomy; cured several months.

Case 88, 1897. Lapujko, *ibid.*, Wratch, 1897, p. 173. Male. Gangrene; pneumotomy (several fragments of lung); recovery.

Case 89, 1897. Tejars, Soc. de Chirurgie, 1897, Feb. 17, and Gaz. Hebdomadaire de Chirurgie, 1897, p. 181. Male, aged 50 years. Pulmonary gangrene with an arterio-sclerosis and general paralysis. Few signs of cavity; partial adhesions, inextensive at the level of gangrenous focus. Resection of three ribs, fourth, fifth and sixth; pleuro-parietal separation; incision of the pleura; lung held with forceps and explored; opening of a cavity the size of a hen's egg at depth of 1.5 cm.; suture of lung to parietal pleura. Death two days later from exhaustion. Necropsy: No other gangrenous cavities.

Case 90, 1897. Tejars, *loc. cit.* Male, aged 33 years. Pulmonary gangrene, acute, eight days' duration. Infectious broncho-pneumonia of two months; right base posteriorly; no signs of cavity; loose partial adhesions. Incision; separation of the pleura; pneumotomy at a point; adhesion; the cavity not found. Death of infection two days later. Necropsy: The cavity is located in the apex; cavity also at the base.

Case 91, 1897. D. M. Moie, London Lancet, 1897, Vol. 1, p. 105. Male, aged 23 years. Gangrene of lung of forty-five days' duration. Acute pneumonia of left lung; adhesions. Horizontal incision two inches long in fifth interspace of left side; escape of fetid fluid and debris; drainage tube; tube removed three weeks after and wound closed one month after. Complete recovery.

Case 92, 1897. Welkowitz, Soc. de Med. de Kieff in Wratch, 1897, p. 175. Male, aged 35 years. Acute gangrene of one month duration. Pneumonia, but no bacilli of Koch; right base anteriorly; signs of cavity; adhesions. Resection of 6 cm. of fifth rib; opening of a cavity, long and narrow, counter-opening posteriorly at the ninth rib, which leads to a pocket the size of an infant's head; these two cavities are separated one from the other. Probable recovery.

Case 93, 1897. Northrup and Medice, N. Y. Med. Jour., Jan. 14, 1897. Female, aged 23 years. Gangrenous abscess of three months' duration. Pleuro-pneumonia; influenza; fetid bronchitis; right base anteriorly; no signs of cavity; partial adhesions, absent anteriorly. Puncture at level of third interspace at the axillary line; many punctures below nipple without result. Incision and resection of sixth rib (3.5 cm.) in the axillary line; partial pneumothorax (not alarming); puncture of the lung; pus at depth of 2 cm.; incision with the scissors; three ounces of pus and gangrenous fragments of lung; second abscess above the first also opened. Recovery; frequent hemoptysis during convalescence; wound completely closed in three months; no hemorrhage; no irritation; drainage. After nine months acute extension with fetid expectorate at this time; recovery without intervention.

Case 94, 1897. Pitts, London Lancet, Vol. 2, p. 915. Child, aged 4 years. Gangrenous abscess of six weeks' duration. Caseous mediastinal glands; left side; pleural adhesions. Rib resected; exploration failed to reveal cavity in lung. Death nine weeks after operation. Necropsy: Caseous bronchial glands, which had opened into esophagus and left bronchus tubercular glands of neck and mediastinum.

Case 95. Pitts, London Lancet, Vol. 2, p. 915. Child, aged 5 years and nine months. Breath fetid, temperature high; hemoptysis had occurred. Caseous mediastinal glands; posterior part of right lung; signs of cavity; pleural adhesions. Exploratory punctures through incision failed to reach cavity. Excision of sixth and seventh ribs in right interscapular region; lung adherent. Child collapsed and died several hours after operation. Necropsy: Caseous abscess cavity size of walnut at root of right lung, opening into right bronchus; caseous glands close to abscess; no signs of tubercle; several patches of gangrene apart from abscess cavity.

Foreign bodies. The subject of foreign bodies in the bronchi is treated here after abscess and gangrene, as they frequently result in abscess and gan-

grene. A great variety of foreign bodies have been aspirated or thrown into the bronchi. The most common variety, in America at least, as taken from the statistics of Dr. Weist, who collected over a thousand cases (*Trans. Am. Surg. Ass.* 1881), is a grain of corn; in frequency this variety is followed by inhalation of the various seeds, as melon, pumpkin, orange, etc., beans, buttons, pebbles and marbles. The effects produced by these foreign bodies on the lung may be divided into primary and secondary. The primary are the dyspnea, pain and coughing; the former may be mild or intense, even to death, depending on the size and location of the body; the pain is usually very severe, and is often a guide to the location of the body; the coughing is persistent, and is often associated with pain. If the body be smooth and of regular outline it may prevent the admission of air to a lobe or even to an entire lung, and by the frequent efforts of coughing and the ball valve action of the body, the lung may be emptied of air and inspiration made painful and distressing; the foreign bodies are retained in their position, principally by the edema of the mucosa; occasionally by the swelling of the seed. Weist's statistics show that the seeds, for the number aspirated, do the least harm; they are the most difficult to find in operation, and therefore should not be operated except when especially indicated. The body may be arrested in the larynx, trachea, at the bifurcation or in a bronchus. Numerous statistics have been published to show that the foreign body has been arrested most frequently in the right bronchus. A comparison of all statistics shows that the arrest occurs in the right and left bronchus with almost equal frequency. The location of the foreign body can often be ascertained by the physical signs. We can at least determine which bronchus is occluded. We are now greatly relieved of the uncertainty of location by the assistance of the X-ray. Many methods have been suggested for the primary treatment of these cases: one of the best is taking advantage of gravity early in the case, *i. e.*, holding the patient by the feet, requiring him to cough as deeply as possible, and slapping the chest forcibly at the time of expiration; this often forces the foreign body out of the bronchus. In upward of 60 per cent. of the recorded cases the foreign body was expelled in this way; as many of these cases are never recorded or even come under a physician's care, it is certain that a much larger percentage recover by this method. Tracheotomy for foreign body has given very good results, but should not be practiced until other means have failed. When the tracheotomy was successful in the removal of the foreign body, the mortality was 6 per cent. When unsuccessful 21.5 per cent. (Weist).

The secondary effects of foreign bodies in the bronchi are even more serious than the primary, as they induce infective processes—abscess, gangrene, bronchiectasis and tuberculosis, which terminate fatally. When it is a metallic or dense substance it can be readily located in a radiograph. The outlines of the abscess can also be defined by this means. G. A. Sutherland reports an instructive case of bronchiectasis, a sequence to an inhaled O'Dwyer tube. The bronchiectatic cavity was opened and the foreign body was not found. The patient died of hemorrhage about three weeks later. Postmortem showed the tube in the right upper bronchus. Multiple bronchiectatic cavities were found.

The following case illustrates the secondary effects of foreign bodies:

Case 1.—March, 1886, Katie M., aged 14, was brought to my office suffering from dyspnea and constant bronchial irritation, following the inhalation of a shelled peanut. It was believed to be in the bronchus of the middle lobe of the right lung; the inhalation was followed by consolidation of this lobe; the expectoration was not offensive, but sero-purulent, tinged with blood. Three weeks later, in a severe attack of coughing, the patient ejected the peanut. The expectoration from that time was scanty but continuous; it was not offensive; the consolidation did not disappear. Six months later she called at my office again; I found her suffering from an acute pulmonary tuberculosis. There was a cavity in the middle lobe of the right lung and bacilli were present in the sputum. Patient died two months later. No postmortem was made. I believe that the foreign body produced the *locus minoris resistentia* for the tubercular infection.

I recall a postmortem made during my internship in 1879, in which a 6-penny shingle nail was the foreign body and the exciting cause of the tuberculosis. The literature on tuberculosis abounds with cases of this class, and the secondary results of foreign body in the lung must not be overlooked though the patient escapes the gangrene and abscess as earlier results.

The presence of a foreign body in the bronchus should be a source of great anxiety until it is removed. The method of its removal has offered fruitful material for speculation and experiment. Primary opening of the bronchus and trachea has been suggested and executed successfully, but the percentage of cases in which the foreign body has been found in the operation has been small, and the results of primary anterior or posterior bronchotomy or pneumotomy do not justify the operation although it often seems indicated. (Truc.) DeForest Willard made extensive and praiseworthy experiments on the removal of foreign bodies in animals, and came to the conclusion that bronchotomy for the removal of foreign bodies should not be attempted. Of 11 operations collected by Tuffier there were four immediate deaths, and in only one of the 11 was the foreign body recovered at the time of the operation. The other cases made only temporary recoveries or had fistulae. The dangers of bronchotomy are, hemorrhage, pneumothorax and infection. From the results of operations and experiments we are not justified in operating for the removal of the foreign body *per se*. These cases should be carefully watched, and early intervention should be made when the secondary changes have taken place, as abscess and gangrene.

TUBERCULOSIS.

Tuberculosis of the lung has been considered a medical and not a surgical disease. In a few instances the surgeon has had the courage to open and drain tubercular cavities in the lung; in a still smaller number he has excised a portion of the lung for the removal of a circumscribed tubercular nodule. Wm. Koch suggested the injection of disinfectants and chemical irritants into the diseased portion of the lung, but they have been used to a very limited degree. With these few exceptions, the disease has been left entirely to the care of the physician. We ask ourselves, what has been achieved in tuberculosis? With the exception of a thorough knowledge of its etiology and pathology, comparatively nothing. We have volumes of literature on the subject, describing its various phenomena, course and terminations. From a sanitary standpoint, since Villemin in 1865 showed its infectious character and Koch dis-

covered the particular bacillus, we are possibly lessening the number of infected; from a therapeutic standpoint we had hoped, and still hope, that tuberculosis may be cured, alleviated or curtailed in its destructive effect by products derived from the tubercular bacillus under certain conditions. The results barely justify a continuation of the hope. Can surgery contribute anything toward the repair of tubercular lesions of the lung? It has accomplished much in the treatment of tubercular lesions of the articular and osseous systems; its results in the treatment of tuberculosis of the peritoneum have been little less than brilliant. The ideal treatment of tuberculosis is eradication; extirpation of the tubercular focus. In only a few instances has the surgeon been able to attack it so as to obtain this ideal result, as in cutaneous, synovial and osteo-tuberculosis. His best achievements have been obtained in cases where he merely placed the tissues under favorable conditions for repair by nature, as drainage of the peritoneal cavity with or without extirpation of the original focus of infection. This necessarily demands the consideration and reparative power of individual tissues when attacked by tuberculosis. Some tissues resist completely its invasion, as the fibrous tissue of tendons and fascia; others, when attacked never tend to repair, as tubercular ulcers of the intestine. In still others, as the peritoneum, the reparative power or resistance offered to the advancement of the disease is great. While a large percentage of the mortuary material is furnished by tuberculosis of the lung the statistics show more than an equal number in which the tuberculosis of the lung was completely cured or circumscribed and did not contribute in any way to the death of the patient. So common are the evidences of repaired, cured tuberculosis in the lung that the Germans have an axiom that every man at the end has a little tuberculosis. In 1000 necropsies, excluding 216 cases that died of phthisis, Osler found undoubted evidence of previous tuberculosis in 59 cases, 7.5 per cent., but Bollinger, Massini and Harris placed it very much higher, ranging from 27 per cent. to 39 per cent., far exceeding those that died of tuberculosis. Bouchard, in his report of postmortems, found that in over 75 per cent. of persons dying suddenly there was some evidence of tuberculous lesions, active or obsolete. A comparison of the postmortem evidences of repair of tuberculosis in the various tissues shows that the lung far exceeds any other tissue in the body, not excepting the peritoneum, in its ability to overcome the effects of tubercular inoculation. This repair is effected by the development from fixed connective tissue cells of resisting capsules of connective tissue with sclerosis and cicatrization of the walls of the cavities. These walls resist the biotic and toxic effect of the bacillus; subsequent degeneration of the encapsulated products takes place, or there is an elimination of the infected focus with its bacilli by necrosis and exfoliation, as illustrated after the use of the Koch tuberculin injections. Investigation shows further, that the so-called "deaths from tuberculosis" are rarely due to the tuberculosis itself, but to secondary infections, that is, it is not the tuberculosis which kills but the mixed infection (pus and saprogenic) of the tubercular centers: the same is true of tuberculosis in other tissues. Do postmortem examinations show us how the encapsulation of tuberculosis is favored or accomplished? Yes, to a limited degree. Does clinical experience, surgical or

medical, offer any suggestions or proofs? Yes, both furnish many if they are properly interpreted. Tuberculosis of the lung is primarily in the great majority of cases a local disease involving but a small portion of one lobe of the lung. Ewart and Kingston Fowler described this process and showed that its extension followed well-defined routes. It advances from the original pulmonary focus by continuity, through the lymph spaces and lymphatic channels and through the blood, and rarely, if ever, along the mucous surface on which the myriads of bacilli are transmitted to the mouth. Pathology teaches us that the effect of the biotic and toxic stimulation of the bacillus is to produce lymphoid cells and a multiplication of the fixed and connective tissue cells of the part: they induce increased deposit of leucocytes and vascular changes, with subsequent necrosis and caseation of the center of the nodule. (Baumgarten.) In tissues containing epithelium these cells also proliferate and the connective tissue cells yield epithelioid and giant cells. (Gaule and Arnold.) Further, the tendency in most tissues in the body is to wall in the destructive process by the formation of a capsule. Tubercular lesions represent reaction of the tissues to the irritation of the tubercle bacillus. In the center of the foyer the irritation is sufficient to destroy the tissues; farther off the irritated tissues build a wall, which in time, makes a cicatricial barrier, plugging up lymphatics and constricting vessels. Leucocytes and wandering cells are attracted by dead bacilli. Living bacilli stimulate connective tissue alone. (Evans.) We have still further abundant proofs that this capsule is destroyed or lessened by secondary infections; that its limiting power is enhanced and favored by physiologic and anatomic quiescence. Its strength and resistance are further favored by aseptic stimulation of cell proliferation in its periphery. The study of the literature on repaired tuberculosis of the lung shows that there was an atelectasis and cicatrization of the pulmonary tissue in close proximity to the nodule; that there was a fibrous and cicatricial development often in the entire lobe which was repaired; that the pleura in the neighborhood of repair was greatly thickened, and effectually immobilized the lung contiguous to it; that the chest wall was contracted and motion of the diseased part was restricted. In other words, the histology of the repair of tuberculosis of the lung in its entire range, from the solitary tubercle to a complete lobe, is made up of a series of defunctionalizing processes, anatomic and physiologic, in every tissue involved directly or indirectly.

Treatment.—Hiller, Berlin, hoped to aid the cicatrization and contraction of the lung by the injection of irritating material into the lung itself, as iodine, iodid of potassium and carbolic acid. His method was tried by Ewald, Pepper and Jablovoski; they failed to obtain good results. Lepine injected sublimated solution into pneumonic lungs and observed a rapid diminution of temperature and improvement in breathing. Contraction of the chest wall for the cure of tuberculosis by means of cauterization of the chest was practiced by Guérin and Vidal. They reported 37 good results in 44 cases. Mosler tried this treatment in 20 cases and while he found great improvement in many he does not report a single cure.⁶⁸ Rive injected iodine and iodid of potassium into the cavities

⁶⁸ Verhand. des Cong. f. Innere Med., Wies., 1883, vols. i-ii, p. 82.

with only temporary relief; he had one fatal result from cerebral embolus.

The pathology of repair of pulmonary tubercular cavities involves certain physical conditions which are peculiar to the chest (they exist to a certain degree in abscess of the bone and brain), namely, the constant resistance of the bony framework against contraction, the effort at expansion of the cavity in each inspiratory act. The best illustrations exist in large empyemic cavities. The bony framework of the chest wall admits of a certain degree of contraction of the cicatricial tissue which makes up the boundary of the empyemic cavity, and then contraction ceases and the cavity remains permanent; as shown in Fig. 20a. This element was overcome by the operations of Estlander, Schede, Delagénère and their modifications, all based upon the same principle, reducing the bony resistance; all artificial means of allowing the obliteration of a cavity by cicatricial contraction and agglutination of its walls. This same resistance to nature's repair exists in every pathologic pulmonary cavity in addition to the ordinary abscess conditions. Allow the wall of the abscess to collapse, to empty thoroughly, and it will heal as other abscesses of the same pathologic character; this I believe is, the keynote to the successful treatment of pulmonary cavities. How to overcome this resistance of the chest wall was a stimulus to my investigations in lung surgery and led to the hope that not only might pulmonary cavities be obliterated by permitting or forcing their collapse, but that primary tuberculosis might be encapsulated by mechanical immobilization of the diseased portion by collapse and enforced rest of the lung as a respiratory apparatus, thus allowing the cicatrization and encapsulation of the tubercular foci; in other words, that tuberculosis of the lung might be treated as we treat tuberculosis of the joints, by immobilizing and enforcing physiologic rest; by enforcing drainage of the secondary products through the bronchi and allowing the ulcer or cavity to heal.

Are we furnished any evidence from the record of postmortems that may be appropriated to support the principle that immobilization and physiologic rest of the lung is favorable to the healing of pulmonary tuberculosis and pulmonary cavities? Yes. 1. Lungs that have been severely involved in tuberculosis, empyema, pneumonia, gangrene or abscess when repaired show a contraction of the chest wall in proportion to the degree of tissue involved; 2. Lungs with tuberculosis that have been compressed by pleuritis exudates, usually sequences of the pulmonary tuberculosis, have repaired the primary tubercular focus during their quiescence; 3. Lungs that have been allowed to collapse following radical operations for the obliteration of empyemic cavities (tubercular in a large percentage of the cases) have healed.

That empyema is curative of tuberculosis of the lung in its early stage I believe can be readily proven. The great majority of empyemas in the adult is the result of primary pulmonary tuberculosis, 83 per cent.; in children tuberculosis is rarely the cause of empyema. In most of the post-mortems on chronic purulent tubercular pleurisy tubercular lesions of the lung or other organs are found, but these lesions are generally quiescent and localized. Empyema from tuberculosis never absorbs and rarely opens into a bronchus. It is a result of mixed infection of the primary tubercular nodule in the lung extending to the pleura. (Strauss.) Of 164 uncomplicated cases of empyema operated by

Koenig, Cabot and Runeberg, 7 remained with fistulae and were incomplete cures, 4 died, and 9 were lost sight of before the cure was complete; all the others recovered. This shows what a favorable termination empyema may have, and considering that it is secondary to tuberculosis in a great majority of cases (83 per cent.) it speaks forcibly for its curative effect upon the lung. Whitney⁶⁹ says "the course of tubercular empyema is peculiarly benign." In 16 cases of pleuritic, non-suppurative effusion, Netter found bacilli in all. It is the prevalent opinion of pathologists that pleurisy from "cold" rarely if ever occurs. Strauss quotes from German authors that "simple" pleurisy is tubercular pleurisy, the true nature of which is not recognized; tuberculosis is the usual etiologic condition in pleurisy; one can say that it represents the real cause in over three-fourths of the cases. Landonzy regards pleurisy from cold as absolutely exceptional. Kelsch and Villard, who investigated 16 cases, say that pleurisy is only a local manifestation of tuberculosis. Chauffard and Gombault inoculated the fluid from 20 simple pleuritic exudates in guinea pigs; 10 died of tuberculosis, the negative cases do not prove that they were not tubercular. Every general practitioner recalls numerous cases of tuberculosis of the lung resulting in empyema or hydrothorax in which there was a complete recovery of the tuberculosis when the empyema and hydrothorax were operated at the proper time. In considering the curative effect of pleuritic effusions upon tuberculosis of the lung we do not include the advanced cases of tuberculosis in which one or more lobes are honeycombed with the disease; here, on account of the consolidation of the lung, it is impossible for the pleuritic effusion to produce collapse and compression of the cavities. When I began this line of investigation I had hoped to find in the reports of the great pathologic institutes detailed accounts of the condition of the primary tubercular focus in the lung and prove my position by them; so far I been unable to find this material, as the postmortem records at my disposal have been defective in this particular. I have called the attention of a number of pathologists to this point and hope shortly to be able to submit accurate descriptions of the tubercular process in the lung with empyema. I do not believe that the empyema or the hydrothorax is advantageous to the tubercular process; by an inhibitory power exercised by the fluid or by a venous stasis, as suggested by Fowler,⁷⁰ of Brooklyn, in his able article, "Surgery of Intrathoracic Tuberculosis." On the contrary, from this standpoint it is detrimental, as it impairs the general condition of the patient. It increases the immediate danger, but favors the ultimate result. Nothnagel and Schrader do not remove the effusions primarily. The force of numbers of operated cases of empyema with permanent cure of the primary tuberculosis of the lung carries conviction that the compression of the lung favors the reparative process, and in this way the pleuritic effusion is curative. Quiescence of the lung greatly diminishes lymphatic circulation and thereby lessens materially the likelihood of the propagation of the tuberculosis to the other parts (W. A. Evans), a fact of great moment, as the tuberculosis is disseminated, from a practical standpoint, almost exclusively by the lymphatics. The methods of obtaining pulmonary quiescence or

⁶⁹ Twentieth Century Practice of Medicine.
⁷⁰ Ann. of Surgery, 1886, xxiv, p. 591.

collapse are: 1. By permitting or forcing the collapse of the lung by separation of the parietal pleura and intrathoracic compression (extra-pleural pneumothorax); 2, by removing the bony resistance and allowing the collapse of the chest wall, thus favoring contraction and cicatrization (thoracoplasty); 3, allowing the lung to collapse by intrapleural injections of gas or fluid. The third method appears to offer more than any of the others. We know that atelectasis of the lung may exist for months, or even years, and the lung be again restored to its function, as shown by West's cases of six to eighteen months' compression with effusion, which were followed by immediate restoration of the lung to full size after removing the fluid; 2, the treatment is simple and painless; 3, the patients will consent when the pathologic condition is most favorable.

Good results were obtained in tubercular cavities with thoracoplasty by a number of authors. De Cazenville and Sengler report recoveries from disease of right apex. Baier reports a temporary recovery. Stewart Tiday supplemented this operation with external compression with adhesive plaster. Coromilas and McEwan favor thoracoplasty.

I have performed the following operation for the purpose of allowing the lung to collapse over a tubercular cavity:

Case 1.—Stephen D., English, age 40, single, clerk, Cook County Infirmary, Surgical Ward 7. Family history: Tuberculosis caused death of mother, two sisters and two brothers. Has had tuberculosis for three years; is emaciated and anemic. The upper lobe of right lung is consolidated; has evidence of a large cavity extending from the first rib to the lower margin of the third with a transverse diameter of two inches; has marked cracked-pot sound; he expectorates two ounces of material with each seizure of coughing; râles over the upper portion of the right lower lobe behind and some râles over the upper lobe of the left lung; no evidence of consolidation in this lobe; tubercle bacilli present; patient had an evening temperature ranging from 102 to 102.5 degrees F. It was decided that he was not in a condition to drain the cavity, and a compression of the lung over the position of the cavity was determined upon.

Operation.—Jan. 9, 1898, chloroform narcosis. Immediately before operation the patient's temperature was 100 degrees, pulse 98, respiration 28; there was a frequent hacking cough. A U-shaped incision was made, beginning at the sternum and the second rib, extending down to the third and then three inches to the right and up again to the second rib; the skin and muscular flaps were elevated; subperiosteal resection of three inches of the second rib; the parietal pleura was detached from the chest wall for a considerable area downward and outward, so as to allow of a greater compression of the lung at that point. The flap was replaced and retained with a deep musculo-cutaneous suture. Very little chloroform was used, as the patient was somewhat cyanotic when the operation began; it was feared he might die on the table. He was placed in bed and rallied rapidly.

At 7 P.M. the day of operation pulse was 108, temperature 101, respiration 32; January 10, 8 A.M., pulse 98, temperature 99.2, respiration 30; slept five hours; cough more constant and less spasmodic with considerable expectoration. January 10, 2 P.M., pulse 100, temperature 99.6, respiration 27. January 10, 7 P.M., pulse 104, temperature 100.2, respiration 30. January 11, 8 A.M., pulse 102, temperature 99.2, respiration 30; slept eight hours. January 11, 8 P.M., pulse 104, temperature 100.2, respiration 52. January 12, A.M., pulse 94, temperature 99.4, respiration 32; slept nine hours. January 12, P.M., pulse 96, temperature 99.8, respiration 34. January 13, A.M., pulse 94, temperature 98.8, respiration 30. January 13, P.M., pulse 96, temperature 99, respiration 32. January 14, A.M., pulse 98, temperature 98.8, respiration 30; slept nine hours; marked improvement in cough and expectoration. January 14, P.M., pulse 100, temperature 99.4, respiration 34. January 15, A.M., pulse 88, temperature 98.8, respiration 32. January 15, P.M., pulse 90, temperature 99.4, respiration 34. January 16, A.M., pulse 84, temperature 98.6, respiration 32. January 16, P.M., pulse 86, temperature 98.4, respiration 33. January 17,

A.M., pulse 88, temperature 98.4, respiration 24. January 17, P.M., pulse 90, temperature 98.4, respiration 24. January 18, A.M., pulse 84, temperature 98.4, respiration 22.

From this time on his temperature, pulse and respiration have been normal; there was primary union of the wound and great depression of the chest over the site of operation. The patient's expectoration has diminished more than half, and is of a light foamy character. His improvement was progressive. He has gained in weight and appearance. April 30 physical examination reveals an entire absence of râles and bronchial breathing on the right side; there is diminished respiratory sound over the seat of depression of the chest wall; no physical signs remain to indicate that a cavity had existed in this locality. On the left side there are râles extending down to the nipple. These physical signs were verified by Drs. George W. Johnson and W. A. Evans. The repair of the lung which has taken place can be seen in radiograph of the right lung; no cavity exists. If the lung in this case were involved to a greater degree I could have inserted my entire hand through the opening in the chest wall into the chest cavity and separated the lung from its adhesions to the wall and compressed it.

Examination July 8 shows that the tuberculosis in the right lung was entirely quiescent. There was not a râle to be heard; the cavity was obliterated; there were some râles over the upper lobe of the left lung and the upper portion of the lower lobe; the patient has had no fever and has had but little expectoration.

Dr. Alexander C. Weiner and Dr. James G. Berry examined this patient with me.

(To be concluded.)

SOCIETY PROCEEDINGS.

Association of American Medical Colleges.

Denver, Colo., June 6, 1898.

[From advance sheets of "Bulletin of American Academy of Medicine."]

The Association was called to order at 10 o'clock A.M., at the Albany Hotel, Denver, Colo., June 6, 1898, by Prof. JAMES W. HOLLAND of Philadelphia, President. The Secretary announced the following members present by delegates: Jefferson Medical College, Philadelphia; Cincinnati College of Medicine and Surgery, Cincinnati; St. Louis College of Physicians and Surgeons, St. Louis; University of Georgetown, Washington; Woman's Medical College, Baltimore; Columbian University, Washington; University of California, San Francisco; Willamette University, Salem, Ore.; Creighton Medical College, Omaha; University of Illinois, Chicago; Medical College of Indiana, Indianapolis; Woman's Medical College, Philadelphia; Detroit College of Medicine, Detroit; University of Louisville, Louisville; Hospital College of Medicine, Louisville; University of Colorado, Boulder; Baltimore Medical College, Baltimore; Kansas Medical College, Topeka; Kentucky School of Medicine, Louisville; University of Minnesota, Minneapolis; Arkansas Industrial University, Little Rock; University of Iowa, Iowa City; Keokuk Medical College, Keokuk; Medico-Chirurgical College, Philadelphia; College of Physicians and Surgeons, Boston; Omaha Medical College, Omaha; University of Denver, Denver; Illinois Medical College, Chicago; University of Southern California, Los Angeles; Milwaukee Medical College, Milwaukee; Barnes Medical College, St. Louis; Wisconsin College of Physicians and Surgeons, Milwaukee; Miami Medical College, Cincinnati; Fort Wayne College of Medicine, Fort Wayne; Syracuse University, Syracuse; College of Physicians and Surgeons, Baltimore; Rush Medical College, Chicago; Western Reserve University, Cleveland; Gross Medical College, Denver; Woman's Medical School, Northwestern University.

On motion, the President appointed the following committee to consider and report on the proposed amendments to the constitution: J. M. Bodine of Louisville, T. H. Hawkins of Denver and H. O. Walker of Detroit.

Prof. MONTGOMERY A. CROCKETT of Buffalo, N. Y., read an essay on "The Developing Method in Teaching Medicine." The subject was approvingly discussed by the following gentlemen, all of whom had slight modifications to suggest: Prof. Chas. G. Stockton of Buffalo, Prof. John Minney of Topeka, Prof. Dudley S. Reynolds of Louisville, Prof. A. Stewart Lobingier of the University of Colorado, Prof. Bayard Holmes of Chicago, Prof. John V. Shoemaker of Philadelphia, Prof. Ernest LaPlace of Philadelphia and Prof. H. J. Herrick of Cleveland.

Professor Crockett was called on to conclude the discussion, after which the Association adjourned until 2 o'clock P.M.

SECOND SESSION.

The Association was called to order at 2:15 P.M. by the President, Prof. James W. Holland. The Secretary read the minutes of the last annual meeting, held at Philadelphia, May 31 and June 1, 1897, which were approved. By request, the Secretary called the roll; twenty-seven colleges answered present by delegates.

The President called past-President James M. Bodine to the chair, and proceeded to read his address. The address was well received, and on motion the Secretary was ordered to publish it and furnish each member of the Association a copy.

Prof. JAMES M. BODINE, Chairman of the Committee on Constitutional Amendments, reported as follows: The amendment proposed for Art. III, Sec. 5, extending the required hours for a year's work to 800, is not a desirable change, and your committee respectfully reports against its adoption. The proposed amendment to Art. III, Sec. 7, by the addition of the following: "*A college not giving the whole four courses of the medical curriculum and not graduating students, but otherwise eligible, may be admitted to membership.*" is respectfully approved by your committee. On motion, the report of the committee was unanimously adopted and the amendment made part of the constitution.

Prof. DUDLEY S. REYNOLDS, Chairman of the Judicial Council, reported as follows: The University of Colorado having been, by recent decision of the courts, obliged to remove its medical department from Denver to Boulder, the question of retaining membership was presented to the Council. The chairman advised as follows: "If you keep your dues paid up, and send annually a representative to the meetings of the Association, your membership is continued until somebody shall prefer, in due form, written charges of violation of some part of the organic law of the College Association, supported by convincing evidence. I would advise you, however, to make no attempt to confer degrees until you are thoroughly equipped for the completion of the required courses of instruction." This advice was accepted, and by your recent action in amending the constitution, the institution is still in every way eligible to membership.

In answer to a communication of Aug. 7, 1897, addressed to Secretary Holmes by Prof. G. M. Waters, M.D., Dean of the Ohio Medical University, Columbus, Ohio, the Council rendered the following decision:

Aug. 20, 1897.

To the Ohio Medical University, Columbus, Ohio:

G. M. WATERS, M.D., Dean:—For answer to your communication of Aug. 7, 1897, addressed to Bayard Holmes, M.D., Secretary of the Association of American Medical Colleges, your attention is invited to the following decision of the Judicial Council in answer to your communication of Dec. 22, 1895: "III. The time requirements of the Association are fundamental," etc. Again, in answer to interrogatories of the Ohio Medical University, of Sept. 4, 1896, the Council decided that "the whole period of time devoted to college work by the student shall not amount to less than four collegiate courses in four separate years in 1899 and thereafter, nor less than three collegiate courses of not less than six months each in three separate years, prior to 1899.

"Second, you can not admit a man to the senior class who has attended but one course of college instruction, no matter how long since that course may have been taken. If he can establish the fact that he did attend one regular collegiate course in an accredited college, you may graduate him after two full courses in addition to that one which he has already taken, provided you do it before 1899. After that time he would be required to take three additional courses. The College Association does not recognize any period of time devoted to practice as equivalent to any part of the prescribed course of study, and can not grant advanced standing to any person upon any ground other than previous collegiate work performed in regular and systematic order."

You say three-course graduates are eligible to registration in Ohio until July 1, 1899. If this be true, the Ohio State Board lowers its standard beneath that of the College Association. No college in good standing can graduate a student in 1899 who has not attended four courses of graded instruction in four separate years, subject alone to the exemptions of Sec. 6, Art. III, of the constitution as amended at Philadelphia, May 31, 1897.

The Mr. Browning of Charleston, W. Va., a copy of whose letter accompanies yours of Aug. 7, 1897, can not now avail himself of the provisions of Sec. 5, Art. III, of the original constitution of the Association of American Medical Colleges,

and you can not admit him for graduation on less than three courses of graded instruction in three separate years, prior to 1899, after which date you can not admit him to the degree of Doctor of Medicine until after he shall have attended four courses of graded instruction of not less than six months each, in four separate years, subject to the exemptions herein cited. It is the judgment of the Council that the date set for the observance of the four years' requirement in 1899, and subsequent classes, begins Jan. 1, 1899.

The study of anatomy can not be completed in less than two separate annual courses. Final examinations in no part of the curriculum are granted prior to the conclusion of the second annual course.

No reputable college can admit the said Browning, or any other student, upon terms different from those specified in the constitution of the Association of American Medical Colleges as heretofore interpreted by the Judicial Council of the said College Association.

If the Ohio State Board of Examiners establish a standard below the minimum of the Association of American Medical Colleges, the Council can simply deplore the fact, but it can not permit your college, or any other institution holding membership in the Association of American Medical Colleges, to violate the fundamental principles set forth in the time requirements of Article III of the constitution of the Association of American Medical Colleges.

JAS. H. ETHERIDGE,
VICTOR C. VAUGHAN,
ALBERT R. BAKER,
RANDOLPH WINSLOW,
JOHN B. ROBERTS.

On motion of Prof. P. Richard Taylor of Louisville, the secretary was directed to publish this decision and supply a copy to each member of the association.

On Nov. 15, 1897, Prof. Pickney French, secretary of the Barnes Medical College of St. Louis, addressed the following letter to Secretary Holmes:

St. Louis, Nov. 15, 1897.

Dr. Bayard Holmes, Chicago, Ill.

DEAR DOCTOR: I have been instructed by the faculty of Barnes Medical College to make the following inquiries of you:

1. Is a medical college that begins its session on January 1, and terminates the same in the following June, strictly speaking, a summer school of medicine, especially when it issues to students, who leave the institution on May 10, certificates of having attended a full course of lectures?

2. If the Barnes Medical College accepted into its regular session a student from such a college, in what way would it be a violation of the rules of the American Association of Medical Colleges?

3. Is there such a rule in force in the Association of American Medical Colleges that requires a lapse of six months' time between the termination of one session, at which a student attended, and the beginning of another which he desires to attend?

4. Is it not a fact that there is a rule only which requires that no two sessions shall be within the same year?

It was the view of our faculty that a summer school of medicine was one beginning its session in the Spring months and terminating its session in the Fall; that a school that began its session, 60 or 90 days later in the winter and terminated its session only six or eight weeks later in the Spring months, was nothing more than a regular winter session of college work. This being our view with reference to question 1, it naturally follows that we can see no impropriety in accepting a student from such an institution, as having completed a regular course during the year prior to the time which he enters and terminates his session with us; hence this expresses our views with respect to the second question.

The asking of the third question seems to be an absurdity, when we reflect that such a rule would interfere with every college of first-class standing in the United States. For instance, the length of session of all high-graded schools is from six and one-half to nine months. The Barnes Medical College began its present session September 13, and will close the same April 12. Rush Medical College has eight months' session, and the medical departments of our State universities, almost invariably nine months' attendance.

In regard to question 4, we suggest that the rule requiring that no two sessions shall be in one and the same year is not violated by accepting students from a college that graduates its students from the middle to the 25th of June, while other colleges graduate their students between the 2nd week of April, and the middle of May.

Barnes Medical College has always taken pride in enforcing the rules of the American Medical College Association, and it is the purpose of her faculty to abide by the decision of your committees, or the officers of the association—we, therefore, submit this question to you, desiring a speedy reply. If you feel like assuming the responsibility of speaking for the association, we will accept your individual views; otherwise we would be pleased to have you submit this communication to such committee as is empowered to pass upon the subject-matter involved and let us have an answer as quickly as is consistent with proper consideration of the subject.

I am very truly,

PINCKNEY FRENCH, Secretary.

The letter being referred to the chairman of the council, the following answer was returned:

LOUISVILLE, KY., Nov. 20, 1897.

Prof. Pinckney French M.D., Barnes Medical College.

DEAR SIR: For answer to your letter of November 15 addressed to Prof. Bayard Holmes of Chicago, I have to say that a medical college which begins its session on January 1 and terminates in the following June, can not be held to comply with the rules of the Association of American Colleges, if it issues tickets for a full course of lectures, on the 10th of May. The time-requirements have been repeatedly held to be fundamental, and it can not be maintained that a student who begins January 1, can possibly have attended one full course by the following 10th of May.

Second, if the Barnes Medical College accepted into its regular session a student with no other qualifications than those above stated, such student could not be credited with having attended one full course, and would therefore be obliged to enter the same grade over again.

The terms of Sec. 5, Art. III, of the constitution, as it existed prior to June 1, 1897, and of the amended constitution, as it now exists, demand that all candidates for the degree of Doctor of Medicine must have attended three courses of graded instruction of not less than six months each, in three separate years, prior to 1899. After the first of January, 1899, all candidates for the degree of Doctor of Medicine must have attended four courses of graded instruction of at least six months' duration, no two of which shall have been in the same calendar year.

The council has several times heretofore decided that "No student can be admitted to a second course of instruction within less than twelve months from the date of the beginning of the first course," and so on through all the succeeding annual courses required of candidates for the degree.

It has also been held that the Ohio Medical University could not receive a student for the second course of instruction in September, 1895, who had completed a first course of graded instruction beginning Jan. 1, 1895, and ending with the month of June, 1895, notwithstanding the fact that the session of the Ohio Medical University beginning in September, 1895, would not terminate until May, 1896. No member of the Association of American Medical Colleges can be permitted to evade the time-requirements with impunity.

If this letter is not entirely satisfactory, I will cause your letter to be copied and submitted to the entire council; I am sure, however, that the council could not, without stultifying itself by a reversal of former opinions, dissent from the opinions herein expressed.

I am, with great respect, yours truly,

DUDLEY S. REYNOLDS,

Chairman of Judicial Council, A.A.M.C.

Similar communications were received from Prof. Samuel O. L. Potter, Secretary of the College of Physicians and Surgeons, of San Francisco; Prof. W. W. Grubbe of the Toledo, Ohio, Medical College; Prof. Wm. V. Morgan of the Central College of Physicians and Surgeons, of Indianapolis; and many individual correspondents, not connected with colleges, all of whom were answered in similar terms. Accompanying the application of the Milwaukee Medical College, for membership, I have received a certified copy of resolutions adopted by the faculty of the Milwaukee Medical College, Jan. 29, 1898, as follows:

COPY OF RESOLUTIONS ADOPTED BY THE FACULTY OF THE MILWAUKEE MEDICAL COLLEGE AT A REGULAR MEETING
HELD JANUARY 29, 1898.

(1) *Resolved*, That beginning with April 5, 1898, the course of study of the Milwaukee Medical College shall consist of four years of six months each.

(2) *Resolved*, That in addition to the winter course, there shall be a spring course of six weeks, said course to be optional.

(3) *Resolved*, That henceforth the Milwaukee Medical College conform to the standard of requirements and rules of the

Association of American Medical Colleges and to those of the Illinois Board of Health.

(4) *Resolved*, That the dean of this school be and is hereby instructed to make formal application for admittance to the Association of American Medical Colleges, with the view of having the school admitted at the next meeting of said association.

All the above resolutions were unanimously adopted.

B. A. BROWN, M.D., Secretary.

Upon the basis of these resolutions the application for membership is approved.

The application of the Illinois Medical College, made through its president, Prof. Randolph N. Hall of Chicago, is approved, with the understanding that the institution will observe all of the requirements of our association.

On the 15th of April, 1898, Prof. P. S. Conner of Cincinnati charged the St. Louis College of Physicians and Surgeons with violation of Article III, Section 7, of the Constitution, specifying that, in March, 1897, the institution conferred the degree of Doctor of Medicine upon Oscar B. Ormsby of Murphysboro, Ill., and M. A. Finley of Mortimer, Kansas, both of whom it was charged, matriculated as first course students at the Illinois Medical College of Chicago, for the season beginning March 15, 1895, in support of which the statement of Prof. H. H. Brown, Secretary of the Illinois Medical College, was filed. A correct copy of the charges and specifications, and the evidence supporting them, being furnished the defendant, it was shown that the Finley named in the charges had attended one full course of instruction in the Kansas City Medical College, Kansas City, Mo.; one course at the Illinois Medical College in a separate year, and two terms in two separate years in the St. Louis College of Physicians and Surgeons; and that the Ormsby mentioned in the specifications, being a pharmacist, and having taken a regular collegiate course of instruction, was entitled to one-half term of advancement in his standing. The institution having acted in apparent good faith, and doubts of the sufficiency of the evidence to support the charges in the face of the testimony for the defense, the council decided that the charges should be dismissed, and they are declared, not sustained.

On the 15th day of April, 1898, Prof. P. S. Conner of Cincinnati, preferred charges and specifications against the Hospital College of Medicine of Louisville, and the Kentucky School of Medicine, Louisville, Ky., charging both of these institutions with graduating at the close of their annual sessions, on the 30th of June, and the 1st of July, 1897, respectively, students who had taken the first course of instruction at the Illinois Medical College, Chicago, during the session of 1895, in violation of Article III, Section 7, of the Constitution. To these charges both institutions plead not guilty. To the specifications they plead guilty, and set forth the facts that students attending a full course of instruction in a regular college, in the year 1895, and a second course in the accused institution in the separate year of 1896, and a third course in the separate year of 1897, thus fulfilled all the requirements of Article III, Section 7, of the Constitution, inasmuch as the Illinois College holds its sessions in the spring and summer only, and the two defendants begin their sessions with the month of January and conclude with the month of June, holding no official terms. In view of this testimony, and these facts, the charges are not sustained, and have been dismissed. In the determination of these matters against the Kentucky School of Medicine and the Hospital College of Medicine, the chairman expressed no opinion, and cast no vote.

Before proceeding further with the report, on request of the chairman, that the association should take action upon so much as had already been submitted, it was, on motion, unanimously adopted.

Continuing the report, the chairman stated that the decision declaring the Medical College of Ohio to have forfeited its membership, having been published, and the institution thereby sufficiently punished, the chairman desired to submit the following: "The council now asks permission to declare that the judgment heretofore rendered against the Medical College of Ohio, declaring its membership forfeited, is now vacated and set aside, and the said Medical College of Ohio is invited to renew its membership in the Association of American Medical Colleges. The chairman desires permission to promulgate the decision."

On motion, the consent of the Association was granted unanimously.

On motion, the report of the Judicial Council, as a whole, was unanimously adopted.

By request of the chairman, all applications for membership from colleges not fully complying with the rules and regula-

tions of the Association, may, upon furnishing satisfactory evidence to the council of a determination in future to make full compliance with all the rules and regulations of the Association, be admitted to full membership in the interval between this and our next annual meeting.

On motion, this request was unanimously granted.

Prof. Henry O. Walker of Detroit, presented the following, which was unanimously adopted:

Resolved, That a committee of three be appointed to ascertain the amount of work being done by the several colleges, members of this Association, and offer such amendments to the Constitution as may seem fit to them, for consideration and action at the next annual meeting.

The president appointed the following committee to take charge of the resolution: Prof. Henry O. Walker of Detroit; Prof. John C. Oliver of Cincinnati, and Prof. Thomas H. Hawkins of Denver.

On motion, the secretary was directed to publish the constitution, by-laws, rules of the Judicial Council, transactions of the association, addresses, and papers presented, and all the decisions of the Judicial Council of permanent value, and to furnish six copies to each college holding membership in the association, and one copy to each of the other medical colleges in the United States; homeopathic, eclectic, and to the secretary of each State board of health and to each State board of medical examiners.

The Association then proceeded to the election of officers, with the following result: President, Prof. Henry O. Walker of Detroit; first vice-president, Prof. H. Bert Ellis of Los Angeles; second vice-president, Prof. Samuel C. Woody of Louisville; secretary and treasurer, Prof. Bayard Holmes of Chicago.

The members of the Judicial Council whose terms expire at this meeting are: Prof. Dudley S. Reynolds, Louisville; Prof. Victor C. Vaughan, Ann Arbor, and Prof. John B. Roberts, Philadelphia, each to serve three years from this date.

The president elect requested to be released from the duties of chairman of the committee, created by resolution, which request was granted, and Prof. E. Fletcher Ingalls of Chicago, was appointed instead.

On motion, the Association adjourned to meet on the last day preceding the next assembling of the AMERICAN MEDICAL ASSOCIATION, at the place chosen by that body.

BAYARD HOLMES, Secretary.

The Medical Society of the State of New Jersey.

One Hundred and Thirty-second Anniversary at Asbury Park, June 28, 1898.

(Continued from page 244.)

In the evening Dr. J. C. APPLEGATE read an essay on REGRESSION VS. PROGRESSION, VIEWING THE GENERAL PRACTITIONER FROM A SCIENTIFIC STANDPOINT.

He did not propose to prove regression on the part of the general practitioner as a whole. With few exceptions, their progressive strides have not been in keeping with surgery and other special branches. The world, it is true, has reached a period in the germ theory that our forefathers never dreamed of, yet the germ theory of most infectious fevers remains still a mystery, and will remain till we have learned the cellular life processes and the ability of cells to resist invasion. Many are in the profession who should be at the plow or the anvil, or *vice versa*. It is the noblest profession because the humblest of the profession is the general practitioner. His responsibilities are great. Is it not true that too often our researches decline at the expiration of our demonstrative course of teaching when it ought to be but the beginning. To be successful we must be perpetual students. During the last decade many evils have arisen tending to belittle the profession. These evils have rapid growth. When the student of today enters upon his field he is confronted by many obstacles. Specialists crowd him; some are *bona fide*, others lack the fundamental principles needed. An eminent physician recently said that in the future each patient will be visited by the family physician and the specialist. Who will then bear the responsibility? The splitting up of the profession into specialties has resulted in great danger to the unity of medical science. A man can not be a successful specialist unless first a successful general practitioner, any more than a man can be a successful contractor until he has labored at and mastered the minor details in connection with the art of building.

The general practitioner often encounters patients who have suffered for a period with vertigo, etc., when inquiry of the brain specialist is made, while the cause of the malady exists

in some remote part of the system, probably of gastric origin, or neurasthenia when the neurologist is consulted; while the origin is local and ought to be in the hands say of the gynecologist. He quoted a case where a lady, aged 45 years, became the victim of epilepsy. Growing worse, she was referred to the gynecologist. Nothing abnormal was found. The nervous specialist was consulted; no relief. But an humble general practitioner, after a careful study of her case, relieved her entirely by antisyphilitic remedies. He did not condemn specialists, only the excessive and incompetent specialism producing discontent among the laity and producing trouble for the physician. Next, the universal use of proprietary remedies, endorsed by members of the profession, does much to check scientific advancement. Even in this age we find learning and science mingling with ignorance and superstition. In the larger cities the public charity abuse, unless modified, will soon cause the extinction of the aspiring specialist who is not connected with one of these. The motive may be good, but the effect is bad. It encourages the wasting of the wages in debauchery. They claim they are not to work as the good people have provided for them. This evil is unlimited and injurious to the laity as well as the profession. The difficulties to be overcome are many, for it is well known that many are deserving but few in comparison with the host of applicants who are in no wise in need. When the boards succeed in correcting this evil their work will be commendable. The general practitioner is thus deprived of valuable material. The method in vogue at the present time, giving greatest semblance to scientific regression, is the result of the relationship between the physician and the pharmacist. When the two were co-operative, things were better. While the physician is engaged in compounding his own prescriptions, or dealing out fixed formulae, the apothecary is prescribing over the counter and practicing the art of surgery whenever the opportunity affords. If he claims to have been forced into this policy it is in a direction where the counter-pressure is strongest; for the physician has but to look around in almost any home to discover numerous remedies, not proprietary, for various ills, compounded by the authority of one of his own pharmacists. The physician has to become his own clerk, assuming responsibilities which belong to the pharmacist. With the beginning practitioner, no better method could be adopted than to handle his own nostrums, as familiarity tends to better his knowledge. The established physician can better afford to leave this work to the pharmacist, utilizing his time in seeking for more accurate knowledge of disease and its remedy. Can we afford to fill our cases with combinations of tablet triturates, etc., furnished by dealers, with foot-notes telling us in which diseases, etc., we shall use them? One of the greatest evils is the indiscriminate use of fixed formulae. He who would be a progressive scientific practitioner must discard such and decide as to what to give his patient after a careful study of the history, etc., of his patient. The science of medicine is a living, not a dead, science. With the suppression of these evils, why should we not note a period in our profession paramount with the historical eighteenth century? He who tells us he has something good to reduce temperature without weakening the heart, and can not name the ingredients, had better remain on the farm. In the golden age of medicine, the eighteenth century, the profession was not overcrowded and there was much less of that one-sided narrow education that obtains today. What shall be the future? Will we continue to approve the use of proprietary nostrums? Or shall we take a bold stand in favor of scientific advancement, making the first decade of the twentieth century an epoch in the history of progressive medicine hitherto unsurpassed? In this the general practitioner should play a most active part. He comes in contact with a disease which claims the lives of thousands annually, one-eighth of the whole human family, regardless of science, more destructive than Vesuvius and more deadly than war. Were he to devote his life to this and establish treatment to successfully combat it, it would be well spent. We can not all be Grosses, Agnews or DaCostas, but he who first is successful in isolating the tubercle bacillus and points out the antidote to effectually neutralize it in the system, will go down in history beside Jenner and his name will be emblazoned on the tablet of fame.

Dr. P. A. HARRIS read an essay on

THE DANGERS OF CERTAIN FAULTY IMPRESSIONS REGARDING THE MENOPAUSE.

This usually occurs between the ages of 40 and 50 years. It is not attained by all in the same manner. Two-thirds skip one, two or three periods for a longer or shorter time prior to cessation. The rest stop suddenly. The average time for this large class to menstruate irregularly is two and a half years. To aid in judging as to what is physiologic and what patho-

logic we must learn the previous habits of the patient. When we find the lengthened period and flow markedly out of proportion to her habit, we will be warranted in assuming that a pathologic condition is present. Endometritis, small myomata, the forthcoming cancer, were doubtless the pathologic causes of the floodings observed. The profession and the laity still have incorrect impressions as to the menopause. Even Tilt regarded as connected with the change many things observable constantly under other circumstances. These are merely coincidents. I believe insanity and melancholia may be a result. Leucorrhœa and painful menstruation should not be credited to it. These disturbances may often be readily relieved. The uterus is a pocket, its cervix a sinus, and when once well inoculated with pyogenic tubercle, etc., it is common for the disease to extend to the fallopian tubes, producing pelvic pain, backache, fever, headache, yet neither of these may be sufficient to cause all so affected to apply for relief. If a patient is nearing the age when the menopause is expected, if she skips a period, has a leucorrhœa, etc., she is apt to regard it as the change. Usually her physician agrees with her, orders some slight treatment, and she returns later with an increase of the symptoms. He then makes a physical examination and may at once discover an unmistakable carcinoma. The question of operation occurs, but the case has been made worse by the delay or neglect; thus, constantly, carelessness causes injury and perhaps loss to the physician. Often, on the other hand, the woman is led astray by her friends, who view all such matters in the light of the change and believe that all will soon come right. Here the delay is the result of the common belief that so many things are due to the change. After carcinoma, the most common trouble is the development of uterine fibroid or myomata. Even small fibroids are often dangerous to neglect, producing emaciation and an appearance as of carcinoma. The expectant treatment must here be abandoned as a cure is almost sure to follow the proper treatment. There is little in the change of life to affect the woman so as to produce serious pathologic conditions. Such may coexist, but are not in relation as cause and effect. In all cases we must make particular inquiry and physical examination; never let the nearness of the menopause influence the opinion to the neglect of every precaution. It is important to detect cancer early. Remove such and the mortality will be largely reduced. While late operation often results in good, yet we have no right to expect it. We should not depend solely upon the fingers, eyes, etc., but use the microscope. Let us then remember that the menopause of itself has little if any effect in either precipitating or arresting the more serious diseases of the pelvic organs; that many of the pathologic conditions are inaugurated and maintained with little regard to that special period in the life of females when the phenomena of ovulation and menstruation are preparing for their final adieu.

Dr. S. A. TWINCH read a paper on

THE EARLY DIAGNOSIS AND TREATMENT OF POTT'S DISEASE.

This paper was well illustrated by pictures on the screen and gave much satisfaction to the society. Spondylitis is a chronic tubercular osteitis which may begin in any part of the spinal column. The symptoms which aid in the diagnosis during the period before deformity appears, he mentioned, as it is then arrest of the trouble may be hoped for. There is a lowering of the vital functions as a premonitory stage. The cervical form shows a rigidity of the muscles around the neck, with difficulty of breathing and occipital neuralgia.

The head is in various positions, generally to one side, the face looking down. The positions assumed are maintained by the rigid cervical muscles. The body turns with the head. Dysphagia is present, caused perhaps by abscess of the vertebra. Such cases are more comfortable when standing or sitting than lying down. Cervical caries is often confounded with torticollis. In caries there is often spasmodic contraction while in torticollis only the one muscle is affected. In dorsal caries an early symptom is rigid back muscles and a prominence of the abdomen. This is nature's method of splinting the spine. The natural flexibility of the healthy spine and the reverse of the diseases is significant. Stooping shows this peculiar gait is an early symptom; he walks with care. Lateral deviation is also a well-known symptom on which great reliance can be placed. This may be slight and easily overlooked. Elevated temperature is constant. The afternoon rise is from 1 to 1 degrees. Paroxysmal pain is frequent at the seat of the disease or in the chest or abdomen aggravated by jar, etc. At night this simulates his disease, by the night cries, or it may be mistaken for stomach-ache. Persistent abdominal pain ought to receive attention although it is not diagnostic of Pott's disease. Absence of pain can not be assumed as absence of Pott's disease. Tiring easily, leaning on chairs or tables means

danger ahead. Dorsal must be differentiated from rachitic and rotary lateral curvature of the spine. Here we have rachitic symptoms, enlarged epiphyses, open fontanels, decayed teeth, etc. Again there is no spasm of the muscles, little or no pain and no elevation of temperature. Lumbar Pott's disease is more difficult to detect early. The occurrence of deformity may be preceded by flattening of the lumbar curve. The attitude is that of lordosis, the gait military and careful. Here curvature is most marked. We may be deceived by the ease with which the child bends the spine to stoop. In Pott's disease the irritation of the lumbar nerves causes psoas contraction, drawing up the thigh. Early, it is difficult to differentiate the two troubles; generally, when the hip symptoms are due to Pott's and the joint symptoms are caused by psoas irritability, the motion in the hip is the loss of extension while abduction and internal rotation are free and not affected. The limitation of motion in one direction is usually sufficient to establish the presence of Pott's disease. Complications are abscesses, the location varying. In cervical it usually opens into the mouth or neck; in dorsal or lumbar in the back or may burrow to open below Poupart's ligament, etc. Watch carefully that the spine is properly supported, remove all weight from the vertebrae. In treatment we must not forget it is tubercular and calls for constitutional treatment. The local affection must be treated by rest; prevent friction, relieve superincumbent weight. We have the plaster jacket and the spinal steel brace. Both have their uses. The first has the advantage of cheapness and can be moulded to fit the body. It is also porous and should be renewed every three months. The jacket is especially suitable for mid dorsal lower dorsal and lumbar Pott's disease. When above the lower dorsal region a jury mast should be used to support the head and shoulders. Accurate adjustment is needed. It must not have any buckles and straps at the will of the patient. If there is to be any fastening, let it be a single row of hooks as on a laced shoe, and care must be taken to bring the edges together. The advantage of the plaster jacket is, once applied it can not be tampered with. We usually keep a child in a closed jacket for three years, then a lace or open jacket another year, taking it off at nights the last six months. For upper dorsal and cervical the jacket is not suitable, not supporting the parts above the disease. It can here only serve as a support for the jury mast. A good apparatus here is Sayer's body brace combined with Schaffer's head-piece. It immobilizes the weight and supports it, thus being superior to a jury mast. The foundation of all jackets is the hip bones, hence it is useless to apply anything till this part of the anatomy is developed to give the support. This is usually by the age of three years. The only satisfactory way of treating very young children is by recumbency and the wire cuirass. A board can be cut to the shape of the child, well padded to be comfortable to lie on. If traction is required a mast can be applied to the upper end. The child is then bandaged to the board, being partially removed morning and evening so that the back may be rubbed with alcohol and treated with powder to prevent irritation. A proper and concise record should be kept to see that the deformity does not increase. The little knuckle at the back may increase so slowly that it is not noticed. A photograph is useful here, or better a tracing with a flexible piece of zinc. If we find increase, no matter how slight, look for the cause. There may be fault in the apparatus, not giving sufficient support to the spine, or the child may be doing too much running around; here recumbency is indicated for a few weeks. For bed patients it is advisable to use apparatus to ensure the child being kept in a recumbent posture. The Bradford frame is extremely simple. It is made of four pieces of gas-pipe put together with elbows. Across the frame are stretched two pieces of canvas between which a space is left opposite the buttock. This frame can be laid on the bed and the child strapped to it. It can be carried all over the house. Abscess depends on location. Post-pharyngeal must be opened as soon as possible because of the tendency to embarrass respiration; elsewhere, better let it alone unless there is a great deal of systemic disturbance or when increasing rapidly. If opening is imperative, after this dress antiseptically and keep clean. Iodoform and glycerin injection are of no use as not reaching the seat of the disease. The formation of an abscess, however, in a case which has been under treatment for some time, suggests that the spine is not being fully and properly supported. The case may need a jury mast, or possibly ambulatory treatment for a time is contra-indicated. Here keeping in bed, wearing the apparatus, will be of inestimable service.

After some routine business the officers for the ensuing year were elected: President, C. R. P. Fisher, Bound Brook; first vice-president, Luther M. Halsey, Williamstown; second vice-president, Wm. Pierson, Orange; treasurer, A. Mercer, New-

ark; secretary, W. J. Chandler, South Orange; corresponding secretary, E. L. B. Godfrey, Camden. Next place of meeting Deal Beach, last of June, 1899.

PRAGTICAL NOTES.

Abdominal Massage is being highly recommended for its diuretic effect in heart disease.—*Bull. de l'Acad. de Méd.*, May 10.

Urethra and Quinia hydrochlorate in the proportion of 1 to 2, form an effective combination for intravenous and subcutaneous injection.—*Gaz. degli Osp. e delle Clin.*

The Almost Invisible Cultures of the Influenza Bacillus become large and prominent if inoculated with the staphylococcus aureus. This fact, recently announced by Meunier, may prove important in the study of micro-organisms.—*Progrès Méd.*, June 18.

Tachycardia in Pulmonary Tuberculosis is always an indication of a rapid course and fatal termination of the disease, according to Sirot. It is symptomatic of an endocarditis from especially virulent bacilli or of a myocarditis from miliary tubercularization.—*Semaine Méd.*, June 8.

Dry Suture of Intra-abdominal Hydatic Cysts.—The cyst is evacuated and wiped dry with sterilized iodoform, then sutured with a continuous suture, followed by the suture of the abdominal wound. The cyst does not fill again, and obliteration is much more rapid and complete than by the usual methods.—*Bobrov of Moscow: Semaine Méd.*, June 7.

Intralesional Synechia is very apt to follow galvanocauterization, but it can be entirely prevented by cauterizing with a few crystals of chromic acid melted on the tip of the probe. The scars thus produced act as insulators, and the process is but slightly painful, much to be preferred to the metal plate and celluloid plates recommended for the purpose.—*Jour. des Soc. Méd. de Lille*, June 18.

Combined Electric Treatment of Sciatica.—Renault has cured 80 per cent. of all his cases by combining the electric bath from a static machine with sparks induced along the spine and course of the sciatic, and faradization of the atrophied muscles in turn until ten to twelve contractions have been produced. The sittings are repeated every day or alternate days. Some are cured in one to five; others require twenty to thirty.—*Semaine Méd.*, June 1.

Cimicifuga Racemosa for Buzzing in the Ear.—Robin and Mendel have found thirty drops a day of the extract of cimicifuga racemosa extremely effective in arresting the noises in the ears caused by direct or reflex stimulation of the auditory nerve, with or without accompanying lesions, ear-plugs, etc. This drug has already proved a good antispasmodic for parturient cases, with marked diaphoretic, narcotic and antipuritus properties.—*Munich Med. Woch.*, May 31.

Inflammatory Processes in Meckel's Diverticulum produced symptoms resembling appendicitis in two cases recently observed by W. Kramer. In one case the trouble was not located until a second operation, when the diverticulum was found occluded by a fruit seed. In the other it had encircled and crooked a loop of the intestines, causing symptoms of ileus. Both were resected after double ligature. One other similar case has been reported by Picqué.—*Munich Med. Woch.*, May 31.

Methylene Blue in Migraine and Nervous Headache has been found very effective in several cases, including himself, by E. Thomson of Dorpat. It prevented the appearance of the severe headache that had previously always accompanied the arrival of the menses in some of the patients. He noticed the increased desire to urinate, and the green tinge of the urine that accompanies its use. It is given with nutmeg aa. 0.1, in a

gelatin capsule. One dose may prove sufficient.—*St. Petersburg. Med. Woch.*, June 11. Migrol, a combination of equal parts brenzcatichuin-monoacetic acid, caffeine and guaiaquin, has also been found very effectual in migraine. Dose 0.5, one to three times a day.

Acute Phosphorus and Morphin Poisoning.—Potassium permanganate has been found effective in neutralizing these intoxications, as it transforms the phosphorus and morphin into harmless oxidated combinations, but, as the potassium itself is poisonous to a certain extent, Schreiber has been testing sodium permanganate, which he finds equally effective and non-irritating. He advises a 0.2 per cent. solution to rinse out the stomach, afterward introducing half a liter and leaving it.—*Cbl. f. Inn. Med.*, No. 23.

Movement Test for Lumbago and Ischias.—L. Minor calls attention in the *Deutsche Med. Woch.*, Nos. 23-24, eleven cuts, to the characteristic manner in which patients raise themselves from a seated position on the ground. With lumbago the motions are the same as in pseudo-hypertrophy of the muscles; the patient bends forward and raises himself by pressing down on his legs, thus climbing to an erect position. In ischias the center of gravity is thrown backward, and the patient supports and raises himself on one hand placed behind him, balancing the other in the air.

Iodin for Infective Gastro-enteritis.—Grosh administers a teaspoon of the following every one or two hours: Tinct. iodine, 15 to 18 drops; aq. dest., 150 grams; simple syrup, 20 grams. The vomiting, pain, diarrhea and fetid odor of the stools disappear with this treatment, which is also effective in icterus, gastric grippe and incipient appendicitis. He has also found iodine an effective disinfectant in typhoid fever, giving six drops tincture in a little sweetened water three or four times a day.—*Semaine Méd.*, June 22.

Milk for Nutritive Enemas.—Some recent tests at v. Leube's clinic show that milk is the best substance for this purpose, as a liter introduced into the colon is readily absorbed without any irritation or pain, or the appearance of albumin or sugar in the urine. No digestion occurs in the colon. The carbohydrates are absorbed best, the albuminoids next and the fats least. The coagulation produced by the bacillus coli interferes with the absorption. This is avoided by thoroughly rinsing out the bowels before administering the milk and by the addition of 1 to 1.5 grams sodium carb. to the liter.—*N. Y. Med. Monatsschrift*, June.

Incompatibilities of Antipyrin.—Tannin precipitates antipyrin in the form of a tannate. Calomel combines with antipyrin to form a very poisonous organic mercurial combination. Antipyrin and carbolic acid also form a combination which forbids their being prescribed together, as is also the case with antipyrin and substances which contain nitric acid, such as amyl or ethyl nitrite. If antipyrin and sodium salicylate are mixed in a powdered form they combine into a gelatinous mass, but they do not affect each other in solutions.—*Vienna Klin. Rundschau*, May 29.

Electric Treatment of Psychoses proceeding from paresthesia of the dura mater, has been found effectual in four cases, by C. Mondino of Palermo. These psychoses commence with tingling, sense of pressure and burning in the cranial vault, followed sooner or later with impairment of the mental faculties, pronounced hypochondria, and various fixed ideas: persecution, an insect crawling under the skin, etc. All these symptoms are connected with the paresthesia of the dura mater, which can be cured with galvanization, when they at once cease. A large electrode is applied over the affected region on the skull, connected with the positive pole with a current of 10 to 15 milliamperes. Six to fifteen sittings accomplished the cure.—*Semaine Méd.*, June 1.

Excision of the Fibula for Sarcoma.—Lloyd, in *Annals of Surgery* for June, reports a case which he believes to be the first example of excision of the fibula for malignant disease, as in malignancy amputation is usually resorted to. In this case there has been no sign of recurrence, and while there is considerable ankylosis at the ankle-joint, the patient walks with very little limp and claims to be perfectly comfortable.

Treatment of Paralysis Agitans, based on the observation that the rigidity and trembling affect the flexors only, while the extensors strive to correct this tendency, has resulted most successfully in the experience of R. Veerhogen (*Jour. Med. de Bruxelles*, 1897, No. 38). He aims to strengthen the extensors and tranquillize the flexors; the former by faradization as powerful as the patient can bear, followed by light massage; the latter by administering atropinum sulfuricum, 0.25 mg., combined with 0.2 gram secale cornutum, and connecting the positive pole of a galvanic current. His patients have resumed their occupations and consider themselves cured.—*Deutsche Med. Woch.*, June 16.

The Deodorizing Properties of Formalin have not been emphasized to the extent they deserve. A tablespoon of formalin in a liter of water will be found the most efficient of all deodorants, non-toxic and absolutely non-irritant. It is especially recommended for offensive discharges, for the anal and genital region, for excessive perspiration of the feet and armpits, to use after dissections, to wash off furniture, commodes, lower part of walls, vessels, etc. The upper part of the walls may be deodorized by evaporating the "formalin water" in a pan over a lamp. The vapors do not affect the inmates of the room.—*Munich Med. Woch.*, May 31.

Value of the Salts of Ammonium.—F. Mohrhoff announces that these salts, and especially the ammonium-silicon fluorid, have a most powerful antiseptic and tonic effect when inhaled; "an ideal medium for the treatment of all diseases caused by abnormal metabolism, as diabetes, etc., as well as affections of the air-passages." As a tonic the effect is more direct and immediate than that of iron. He has invented an improved inhaler which renders its application more convenient, but does not describe its features in his communication to the *Deutsche Med. Woch.* of June 9, merely mentioning the maker.

Cocain Intoxication.—Weigand has collected 250 cases of acute cocain intoxication, twenty-one fatal. It is impossible to establish a maximum fatal dose for man, as the tolerance varies widely. The most dangerous application seems to be large amounts applied to the mucous membrane. Seven deaths followed its use internally, two in the rectum (*Cbl. f. Chir.*, May 28). Bozza reports, in an Italian journal, that the hypodermic injection of physiologic salt solution immediately after the ingestion of nearly twice the fatal dose of cocain will preserve dogs from intoxication. He therefore recommends hypodermoclysis for cocain intoxication.

Urethral Pencils must be made of a substance that will not melt and run out. A combination of two parts cocoa butter, one part lanolin is recommended in the *Bulletin of the Bordeaux Soc. de Pharmacie* for May. This is melted and set aside until needed, when it is remelted and the medicament blended with it. A glass tube is then inserted in the fluid mass and it is drawn up into the tube by suction with the mouth. The other tubes are filled in the same way, and when the fluid is hardened, but not really cold, the contents of the tube are pushed out with an iron rod, 3 mm. in diameter, which fits smoothly inside the tube. The pencil is received on a marble or glass slab. They can be delivered at once, but are not perfectly solid until the next day.

The Success of Salophen in Curing Pruritis is proclaimed by several writers in the *Dermat. Ztschft.* for May. Salophen is a combination of salicylic acid with acetylparamido-phenol, and

passes through the stomach unchanged, to be slowly split up by the alkaline secretions of the intestines. It cured a number of chronic rebellious cases accompanying moist eczema, diabetes, urticaria and psoriasis, and checked any recurrence of the pruritus. The dose is 3 to 6 grams a day. Drows ascribes the cure to it in a couple of cases of gonorrheal rheumatism out of five treated. According to Drasche, it produces copious perspiration and the skin is found scattered with minute crystals of the same form as salophen crystals. All state that it does not disturb the digestion.

Cheese in Nervous Dyspepsia.—The dyspepsia accompanying herpeticism or neuro-arthritis is very deceptive in its manifestations; patients complain of heart, lungs, brain affections, vertigo, paralysis, but the true trouble is indicated by the triad; cold extremities, insomnia during the middle of the night and fatigue on waking in the morning, with, occasionally, pain in the sternal or intercostal regions, palpitations, drowsiness in the evening, etc. Lancereaux forbids to such patients everything fried, acid or uncooked, wine, chocolate, colored sauces, fruit and bread, except the crust or toast. But he recommends the cheese of the Brie, Camembert and Roquefort varieties, a little very fresh butter, eggs, broiled or roast meats, etc.; for breakfast a crust of bread, soft egg and Brie cheese. Water is the principal beverage, with a little tea, coffee or mild beer, or ordinary beer diluted with Vals water or very weak brandy water.—*Union Médicale*, May.

Treatment of Prostatic Retention.—Rochet bases his treatment on repeated catheterization, provided it can be done with ease and is not required too frequently, in which case a permanent catheter should be inserted. If catheterization is too difficult and urine is retained, with fever, pain, hemorrhage, etc., the bladder should be punctured again and again, or temporary drainage of the bladder arranged, after which the congested condition may pass away and the normal flow of the urine be restored or catheterization become easy again. Chronic cases may require perineal drainage, dilatation and perineal prostatectomy. For extreme cases with infective suppurating cystitis, suprapubic cystostomy is the only means of relief. The importance of immediate investigation by both abdomen and rectum in case of any disturbance in the functions of the bladder in elderly men has recently been emphasized by Englisch, who adds in regard to catheterization that the "longer the retention has lasted, the more slowly should the bladder be emptied."—*Cbl. f. Chir.*, June 11.

Treatment of Lupus with the Roentgen Ray and Concentrated Sunlight has passed beyond the experimental stage. H. Kümmel of Hamburg, announced at the German Congress of Surgery that he had positively cured sixteen patients to date with exposure to the Roentgen ray for fifteen to twenty minutes, twice a day for a period of four weeks to several months. The sound skin is protected by a light sheet of lead or stanniol, cut to expose only the lupus patch, with the tube from 20 to 40 cm. distant. All irritation of the skin is most carefully avoided, and exposure individualized to prevent the slightest dermatitis. The lupus patches heal over with a smooth surface scarcely to be distinguished from normal skin. Similarly favorable results have been secured by Finsen of Copenhagen, with contracted sunlight or electric light, excluding the heat rays. As blood prevents the passage of the rays he expels it from the point to be treated by a convex, transparent glass saucer, strapped on tightly. He reports a large number cured from one to two years, but his process requires months of treatment, as only a small point can be treated at a time. The combination of this method with the Roentgen ray treatment promises remarkable results. The latest tests fail to confirm the bactericidal action of the Roentgen ray. Its effect on lupus is evidently due to some still undetermined influence on the lupus tissue, possibly electro-chemic or trophoneurotic.—*Cbl. f. Chir.*, July 2.

SELECTIONS.

Medical Education in Mexico.—In 1578, a chair of medicine was initiated in the University of Mexico—that institution being then twenty-five years old—and was the first of the kind to be established in the New World. It was called the *prima* or morning class, and the professor was expected to cover the whole field of the science, as it then was taught; and it was said that he managed to do so in the course of four years. The student, as the custom then was, was required to serve a pupilage under some practitioner for a longer or shorter period. Candidates had previously to study Latin and to go through the course of arts, and astrology or mathematics, and to obtain the degree of Bachelor of Arts. In 1599 a second chair of medicine was founded, which was called *vesperas*, or evening class. In 1661 chairs of *methodus medendi* and of anatomy and surgery were established; and later a class of dissection and operative surgery was added. At the end of the curriculum the student obtained the degree of Bachelor of Medicine; subsequently, after a fresh examination, that of licentiate; and finally, after an interval, that of doctor. In 1768 a Royal College of Surgeons was established on the model of similar colleges then existing in Cadiz and Barcelona. In this college practitioners of a lower grade were trained; they were called "Romancist surgeons," to distinguish them from the "Latin surgeons" who studied in the University. At this College, also, phlebotomists, dentists, bone-setters, midwives, etc., picked up such scraps of knowledge as were required for the exercise of their several functions. After a time an ordinance was made that no one should be allowed to matriculate in this school who did not know Latin. In 1830 a further step was taken for the improvement of the professional education of the surgeons in the shape of an enactment that no one should be admitted to the school of surgery who had not previously obtained the degree of Bachelor of Philosophy. In 1831 the two branches of the profession were finally amalgamated; all candidates were required to submit to examination in medicine and surgery, and the faculty conferred a diploma in both, instead of the various diplomas of physician, "Latin surgeon," and "Romancist surgeon," which had previously been given. The numerous political changes which swept over Mexico in the years following 1833 affected the medical school, which was several times closed, and more than once in danger of destruction. Largely owing to the public spirit of its professors, however, it managed to survive, and under the enlightened administration of General Diaz, it has now developed into a highly efficient teaching institution. Before 1833 it had 11 professorships; from that date to 1877 only 5 were added. From 1877 to the present date 10 new chairs have been established, without counting a large class of clinical teachers, assistants and prosectors.

Cesarean Section.—Reynolds (*Am. Jour. of Obstet.*, June) considers Cesarean section justified in all cases where a mechanical obstacle renders delivery, in an otherwise healthy woman, more than ordinarily difficult and dangerous. His experience covers twelve years' service in a clinic which delivers 2500 women every year. He believes that symphyseotomy should be restricted to the class of cases from which he would exclude performance of Cesarean section, *i. e.*, cases of moderately contracted pelvis in women not previously healthy, or in women exhausted by long labor. His conclusions are: 1. That in women who are the subjects of visceral disease or other previous ill health, and in women who are exhausted by long labor, the maternal mortality of the Cesarean section is too great to allow of its performance in the interest of the child alone. 2. That in primiparæ with moderate contraction the decision whether or not the Cesarean section should be performed as an alternative operation at the beginning of labor in prefer-

ence to an attempt at an intrapelvic delivery, is a decision which is intrinsically so difficult that it should be attempted by none but the most experienced obstetricians. 3. That in most cases of moderate contraction in primiparæ it is best to wait until the progress of labor teaches us which is to be the safer operation in the given case. 4. That when any healthy woman has lost one child by a difficult operative labor in the hands of an expert she should in the next labor be prepared for Cesarean section and delivered by it, unless the course of labor shows that from some changed condition, *e. g.*, a small child or a more favorable position, a forceps delivery is likely to be easy. 5. That when any case occurs in the practice of the comparatively few men who are really experienced in both obstetric and abdominal surgery, in which an attempted forceps operation proves to be exceptionally difficult and version promises no better results, the forceps operation should be suspended, and if the fetal heart is undisturbed, should be abandoned in favor of the Cesarean delivery. 6. That in very small pelvis, *e. g.*, those under three and one-fourth inches in the conjugate, the Cesarean section in favorable circumstances is the operation of preference.

The Treatment of Carbolic Acid Poisoning with Vinegar.—The following case is related by Dr. Stevenson in the *Indian Medical Record*: The patient was a girl 18 years old, who said she was subject to "fits." On Aug. 3, 1896, she was taken with one, and when the physician saw her she was in a semi-conscious condition and frothing at the mouth. She had vomited slightly, and the vomited matter had a sour smell, but no carbolic acid odor was observed. She regained consciousness, and a bromid draught was administered. She gradually became worse and another physician was called to see her. He diagnosticated the case as one of carbolic acid poisoning and as he could not rouse the patient nor get her to swallow anything he ordered her to be removed to the hospital. On admission, she was still wholly unconscious, cyanosed and nearly pulseless. The lips and tongue were discolored and the breath had the odor of carbolic acid. The physician gave her a hypodermic injection of strychnin (one-eightieth of a grain). He then passed a soft stomach tube, washed the stomach out with equal parts of vinegar and water, and followed this with about six pints of warm water. He then gave her five ounces of milk and an ounce of brandy. She was then put into bed and kept warm. She gradually regained consciousness, and a few hours afterwards was able to speak. She was fed on Benger's food, milk and soda-water for the next three days. She did not vomit or complain of any pain. Carboloria was present for two days. The author states that he was led to use vinegar in this case by Professor Carleton's suggestion in the *Practitioner* of August, 1896. He can not state definitely how much carbolic acid was taken. The long period of unconsciousness, the rapid recovery, and the absence of discomforting after-effects speak well, he thinks, for the vinegar, and he is of the opinion that it should be given a fair trial, especially as it is a remedy easily obtained.

Primary Tuberculosis of the Spleen.—Quenu laparotomized a woman of 21 years, in April, 1897, for a painful tumor of the spleen. She had previously been affected with cervical adenopathy. The lower portion of the organ was found grayish-white and fluctuating, the seat of a tumor the size of a man's head, but adhesions rendered extirpation impossible, although he was able to bring it into the abdominal wound and suture it to the parietal peritoneum. An incision only brought a few drops of fluid. A couple of pockets were excavated with the fingers, removing a fibrinous substance, and drains inserted. A fetid fluid was discharged through them and, in a few days, the wound filled up with a greenish, granulating mass, which was removed every day with the scissors or thermocautery, in fragments. This elimination of the mortified substance continued into August, but the wound definitely healed over by September. The Koch bacillus was noted in the tissues removed. In May a tumor of tuberculous origin also appeared in the supraclavicular region, which was promptly extirpated. —*Rev. de Gyn. et de Chir. Abd.*, March and April, 1898.

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$ 5.00
Foreign Postage	2 00
Single Copies	10 Cents

In requesting change of address, give old as well as new location.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
No. 61 Market Street (Occidental Bldgs.), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 6, 1898.

UPON THE EXISTENCE OF A MINUTE MICRO-
ORGANISM IN CASES OF CIRRHOSIS OF
THE LIVER.

While working with the so-called Pictou Cattle Disease, in 1894-5, Professor ADAMI of Montreal, obtained from the livers and abdominal lymph glands a characteristic micro-organism. The striking feature of this disease is an extensive cirrhosis of the liver, accompanied by swelling of the periportal and retro-peritoneal lymph glands, with some ascites, and with follicular ulceration of the fourth stomach. The recognizable symptoms, the most marked of which is falling off of the milk, which becomes bitter when heated, occur shortly before death. Hence the cirrhosis must have been advancing for some time without producing any symptoms.

The microbes referred to are very difficult to stain, that is to say, they stain easily but lose their stain with extreme facility. They are also extremely minute, being barely recognizable with a fifteenth immersion lens.

The presence of these micro-organisms in the cirrhosis of the liver of Pictou Cattle Disease led ADAMI to examine cirrhotic human livers for the purpose of observing whether or not the same or similar micro-organisms occur there. It will be recalled that HANOT and French pathologists in general have for some time held that the large, smooth cirrhotic liver with jaundice (hypertrophic cirrhosis) is of infectious origin. No one, however, has ventured to state that the more common, so-called atrophic cirrhosis, is due to

microbes, the general opinion being that alcohol and other irritants, by causing a chronic gastro-enteritis, lead to the absorption of toxic bodies from the food, which toxic substances induce, as they are taken up by the portal blood, a proliferation of the portal connective tissue.

Professor ADAMI's study of human atrophic cirrhosis was met by many difficulties, the chief one being the difficulty of securing a satisfactory and positive stain. In favorable instances, however, he was able to make out that certain fine granules in the liver sections resolved themselves into large numbers of minute micro-organisms of the character observed in Pictou Cattle Disease, but smaller. In the main they were present as diplococci, with slight halos around them. Many of the forms resembled small gonococci, but variations in size of the micro-organism occurred. Some of them resembled short bacilli.

ADAMI has not yet been able to elaborate a perfect stain. The most satisfactory procedure so far consists in placing the sections for a minute or two in a weak solution of acetic acid, then to wash out the acid, and after passing the sections through absolute alcohol, to place them in a solution of methylene-blue and anilin oil. Here they are left for half an hour. They are then transferred for fifteen seconds into a mixture of two parts anilin oil and two parts xylol, and then into xylol. This method gives fair results for immediate study but does not yield permanent specimens. By this method the bacteria are seen plainly in the newly-formed connective tissue, and also, without doubt, in the liver cells. Some of them do not stain perfectly, remaining brownish, and these are probably dead.

At the time of making this report ADAMI had come across this micro-organism in every case of advanced hob-nailed liver examined (five cases) and he would go so far as to state, that in a number of cases, at least, of atrophic cirrhosis, there is present a minute micro-organism resembling closely the one in the infective cirrhosis of cattle.

Since making his first report ADAMI has had occasion to study material from Rush Medical College, Chicago, and the Johns Hopkins Hospital of Baltimore, and in all of the Chicago cases, as well as in ten well-marked examples from Baltimore, he was able to recognize the appearances above described.

A fuller description of these most interesting observations will be presented at the meeting of the British Medical Association at Edinburgh, by Dr. Osler.

CONCERNING THE SO-CALLED APOPLEXY OF
THE UTERUS.

The condition described by CRUVEILHIER, and later by ROKITANSKY, KLOB and DITTRICH, under the term of apoplexy of the uterus, has not been given any consideration in the ordinary gynecologic text-books.

1 Montreal Medical Journal, July, 1898.

C. VON KAHLDEN,¹ of Freiburg, has recently described several cases which he has observed anatomically and subjected to a thorough examination.

The anatomic condition is, in its principal features, the same in all cases. While the size of the organ may vary, as well as the size of its cavities, there is found everywhere, in the mucous membrane of the uterus, more or less pronounced hemorrhagic infiltration, which in the least marked instances remains limited to the mucous membrane, while in the more advanced cases it extends deeply into the muscular coat. The cervical mucous membrane is always free from extravasations.

The most striking as well as most characteristic features in these cases are the changes in the vessels in the outer half of the wall of the uterus. These changes are regarded by VON KAHLDEN as arterio-sclerotic in nature. The arteries present segmentary semilunar, and even annular, calcification of the media, with advanced narrowing of the lumen, the intima being sometimes ten times as thick as normal, the muscle granular, more rarely the seat of a hyaline degeneration. This thickening in the intima very often reminds one of the endarteritis of syphilis. In advanced cases the calcification may have involved the intima. The veins in the vicinity of the diseased arteries are greatly dilated and filled with blood: the muscle of the uterus being sometimes necrotic and sometimes the seat of atrophy and connective tissue substitution. These various changes are finely illustrated by means of lithographs of colored drawings. VON KAHLDEN does not regard the hemorrhages into the mucous membrane as due to rupture pure and simple, because the diseased vessels are so far away from the inner lining. He is inclined to the opinion that the hemorrhage results from retrograde changes in the blood, which view, although it seems rather unreasonable on account of the numerous anastomoses of the uterine arteries, yet appears to be well substantiated by the considerations presented in the article.

The etiology is entirely obscure. Among the conditions that might be brought into question, although any direct connection with any one of them has not yet been established, may be mentioned pregnancy, involution, inflammatory puerperal processes, menstrual congestions, and old inflammations. Under all conditions the cause has to be sought in local changes, because the arterio-sclerotic process described runs its course independent of arterio-sclerosis elsewhere in the body.

The diagnosis is not easy. The hemorrhages constitute a prominent feature. With a curette it would often be impossible to bring away any of the typically diseased vessels, and even should this be the case the condition may be readily confounded with carcinoma and inflammatory processes. The hemorrhages and the old age of the patient are facts that at once pre-

possess the physician in favor of a carcinomatous process, and the extravasated masses of blood very often press together the glandular tubules in such a way that they resemble not a little the glandular masses of carcinoma. It is the fact that this process may be confounded with carcinoma that has led us to call attention to it.

SALINE INFUSIONS.

It is surprising that the use of saline infusion, a method so incomparably superior to all others in the treatment of hemorrhage and shock, should meet with such restricted use among the general practicing physicians. There are perhaps few hospitals that are not provided with the apparatus and the sterile salt solution necessary for infusion at ten minutes' notice, yet the general practitioner seems almost never to class it among his methods of combating hemorrhage, shock and septicemia. He feels his duty done when he has filled the patient with strychnin, whiskey, digitalis, nitroglycerin or coffee. The effects of intravenous and hypodermic infusions are so immediate and so absolutely life-saving in many instances that nobody who has ever seen its use can doubt for a moment its superiority as a surgical method. The greater the pity, then, that the general practitioner of the country and city districts, nay many a surgeon in hospital practice, should fail to place this among his everyday practices in the treatment of his cases. It is needless for the country practitioner to say that he rarely has the opportunity for its use, because he certainly has cases of typhoid with hemorrhage, postpartum hemorrhage, septic cases, and many cases of severe injury to treat in the course of a twelve-months. He need not cast aside the hypodermic syringe, the stimulants and all other means of combating shock, but in omitting the use of the infusion of salt solution he is omitting the most nearly life-saving agent that he ever can have at his command. To say that he has not the surgical skill is absurd. Hypodermoclysis, or the injection of salt solution into the loose subcutaneous tissues, is perfectly easy and simple in any private residence. The physician needs a fair-sized aspirating needle (or his hypodermic needle will do) and three feet of good rubber tubing. These should always be in his bag and when occasion arises it is perfectly simple to call for a clean half-gallon stew pan, fill this with clear water and make a normal salt solution by adding one drachm of common table salt to the pint of water. The tube and needle are now placed in this salt solution and both solution and tubing sterilized by boiling for a few minutes. The salt solution can be quickly cooled to a temperature of 105 to 110 degrees F., by placing the vessel in cold water, and the syphon is established by means of the rubber tubing which has been connected to the needle. When the fluid is flowing and all air is expelled from the tube, the needle is thrust

¹ Ueber die Sogenannte Apoplexia uteri, Zeigler's Beiträge, xxiii, 1, 1898.

into the subcutaneous tissues of the chest, axilla or abdomen; and from a pint to a quart of the salt solution allowed to slowly run in. This puffs up the skin and forms a tumor, but the solution will absorb rapidly and an abscess will almost never form. The patient revives as by magic, unless his vital processes are at such a low ebb that the solution cannot be absorbed, when intravenous injection will be indicated.

The intravenous injection should not be more formidable to the practitioner. Anybody ought to be able to find a vein in the arm or the leg, and there is practically no danger in looking for it. Having found the vein, a small canula of metal or glass should take the place of the needle used in the method previously described, and this inserted into the proximal end of a vein which has been one-third or one-half divided by a clip of the scissors. The canula is held in place by a ligature previously thrown around the vein and the fluid may flow in rapidly, with, of course, much more rapid effect than could be expected in hypodermoclysis. It is folly to think of either one of these methods as a difficult process, and furthermore, no matter how difficult it may be, it is the duty of every practitioner to understand its use. Should a new specific drug for a cold or pneumonia be placed on the market, every practitioner in the country would prescribe it and, furthermore, his patients would demand it. The use of saline infusions is as specific in its field of usefulness as any drug that we possess.

Salt solution is the one preferred by almost all surgeons, and the addition of the chlorid of calcium and potassium, as in RINGER's fluid, are found to be unnecessary. Pure water has been used without damage in emergencies. The percentage of salt need not be accurate, and is obtained by adding 3i of common salt to Oi of water. One to three quarts may be given, and it is well to remember that it is hard to give too much since experiment has shown that 40 to 80 c.c. per minute are not toxic. The temperature in the supply reservoir should be 105 to 107 degrees, in order that the temperature of the fluid may be approximately 100 degrees F., when it enters the vein or subcutaneous tissue. The injection may be repeated a number of times should the patient's condition fail to improve or become worse after a temporary improvement.

There are many cases of hemorrhage where the patient is so completely exsanguinated that it seems the only possible benefit can come from the transfer of oxygen-carrying blood from another man or animal to our patient. Yet, it must always be remembered that in the majority of cases it is impossible for a patient to lose enough red blood-corpuscles to impair the respiratory function. He invariably faints first, because the circulating blood is insufficient to supply the heart, the respiratory centers and the brain. The real need is to furnish enough fluid to suspend the

remaining red blood-cells for circulation through the system and restore a normal amount of circulating fluid for the heart and arteries to act upon. As has been said before, a 6 per cent. salt solution answers every purpose of complex solutions that attempt to reproduce the chemic composition of normal blood serum; it is always at hand and easily made; furthermore, it can be boiled for sterilization without changing its composition. The transfusion of blood is entirely abandoned as a dangerous procedure and as one that is inferior to saline infusion even when it works without accident. As previously stated, there are enough red blood-cells left to perform the function of respiration.

In conditions of shock without great loss of blood, the entire nervous mechanism of organic life, according to GROENINGEN, is raised to a maximum stimulation, and the inhibitory centers are paralyzed; the sensations are dulled and the motor functions are suspended; the depraved metabolic processes give rise to a weak heart and respiration and the blood fails to circulate. It is impossible in such a condition of shock to at once restore these over-stimulated nerve-cells from their paralyzed state to one of normal activity, but by restoring the normal volume of blood, nutrition is restored to the cells, there is an increased heart and respiratory function and the metabolic processes throughout the body are restored during the time that these nerve-cells are resting.

We have for our justification of the use of infusion in conditions of septicemia the two important facts of the increased activity of the leucocytes and the increased activity of the skin and kidneys whereby the toxic products may be destroyed or eliminated. There is the further advantage of diluting the poison in the blood.

The exact action of saline infusion in any condition has not been as accurately worked out as the importance of the subject justifies, but whatever it may be, there is no other remedy comparable for the relief of the symptoms of shock and hemorrhage. The changes that take place in the patient are immediately perceptible. There is a restoration of the normal heart action, pulse volume and respiratory function; the unconscious and paralyzed patient opens his eyes, speaks and invariably begins to move. In one to two hours there is a rise of temperature not over 100 degrees F., and there is a diuresis with no albuminuria. Most important of all, the restoration of function is permanent. With such points as these in favor of a remedy it is difficult to see how it can fail to meet with universal practice.

DOUBLE HEADED MONSTERS IN FICTION.

The utilization of pathologic data in fiction has become so widespread that the neglect of the rich field of teratologic conditions must appear rather mysterious. Considering the casuistic discussions of

the marriage of the Siamese twins and of the marital status of the pyropagic (backunited) "Double-Headed Nightingale," it seems strange in these days of realism, that so little use should be made of double-headed monsters in fiction. This appears particularly unaccountable, when the legal, amatory, ethic and marital complications thereon resultant (capable of producing such beautifully intricate plots) are considered. The "Double-Headed Nightingale" was legally decided to be two persons; marriage of one man to whom would result in bigamy. Under certain legal opinions in Illinois, simultaneous marriage with more than one woman does not constitute bigamy in that State. Under this construction of the Illinois statute regulating marriage, the marriage ceremonies must be separate to constitute bigamy. Marriage in Illinois with the "Double-Headed Nightingale" could easily be made a practical simultaneous procedure and hence legal. Under the intricacies of the New York divorce law, a New York marriage could, under certain technicalities, be easily set aside in Kansas, and a second marriage thereafter would be legal. As the first marriage was still legal in New York, a man could easily have two wives in that State without committing bigamy. One half the "Double-Headed Nightingale" could be married in New York and the other (after proper divorce proceedings) in Kansas, both halves being legally wives of the same man in New York. Despite those tempting literary possibilities fiction has neglected this field. BESANT employed, it is true, a double monster, but only as a portent in "For Faith and Freedom." Through the pages of that clever parody, "King Solomon's Wives," flits a double-headed caricature of RIDER HAGGARD'S terrifying Gagool. With these exceptions, fiction has until lately neglected the fertile literary possibilities of female double-headed monsters.

It was reserved for an Ohio physician to demonstrate the brilliant outlook for fiction in this particular. Dr. W. C. COOPER of Cleves, Ohio, has proven the great value of the double-headed monster in fiction in his "Mystery of the Wetherston Mansion." His heroine is an atlodymus with two heads united at the neck to a single body. This monstrosity is the child of a wealthy judge of Southern Illinois, who is a man of broad, general culture. Dr. COOPER is called to attend the wife of the judge in confinement. Owing to severe dystocia the patient becomes moribund. Whereupon Dr. COOPER performs Cæsarian section, delivering an atlodymus thus described by himself: The heads and necks were entirely distinct, the union of the necks occurring at their junction with the thorax. It was highly probable that tracheæ, esophagi and blood vessels became uniform and common on entering the body. Young as this infant was, it was plainly evident that each head was directly individual. It could be seen too that the child was ambidextrous. There were undoubted signs too that

one head bordered strongly on the brunette and the other on the blonde type. They could nurse separately or simultaneously. The only difference was that when both nursed at once the appetite was satisfied twice as quickly as when only one of them was fed. The body was that of a girl.

The Southern Illinois village, where the judge resides, is cursed by the usual spinster gossip, with prurient prudery and mendacity. One of these, loitering around the keyhole of the lying-in room, hears what she considers suspicious remarks by Dr. COOPER. An attack of cholera infantum, due to an uncleaned nursing bottle, calls Dr. COOPER (during the week following the delivery) to the mansion to attend the monstrosity. On his way back to his office he is waylaid by the female "Paul Pry" aforesaid. Injudiciously, but professionally, hoping to check her inquisitiveness, he informs her that the monstrosity is dead, whereupon she has him arrested for murder. Through the judge's influence and cash, the charge is withdrawn. Popular rumor imputes the death of the monstrosity (which is assumed to have taken place) to natural causes. The monstrosity is, however, brought up in the seclusion of the mansion, to womanhood, and carefully trained by a governess sworn to secrecy. The judge, who has not recovered from the shock of the death of his wife and the birth of the monstrosity, finds from growing age and mental infirmity that he needs a private, confidential secretary. A young lawyer named Jack obtains the place, and in most things, the judge's confidence. The secret of the monstrosity is, however, kept even from him. As the judge has exhibited continuously increasing mental depression from the time of his wife's death, his suicide is not a remarkable outcome. The agitation in the household reveals for the first time the existence of the monstrosity to the private secretary. The heads of the atlodymus have been called Alice and Anna.

"Jack falls hopelessly, helplessly in love with Alice. In the innocent frankness of her unsophisticated nature she confesses without a moment's hesitation that his passion is fully reciprocated. Alice and Anna are nearly inconsolable over their father's death. Alice, however, rallies from the shock as time drags by. She has Jack's love to lean on and feed on. Not so with Anna, who being in a decline before her father's death, receives from that calamity a tremendous downward impetus, and has not the tonic of a lover's helpful sympathy and counsels to brace her. It becomes rapidly evident that she is sinking back to God. She is absolutely certain that she can die without involving the death of her sister. Alice herself also feels sure of this. It seems that some infallible intuition guides them to this conclusion. Since her father's death, and especially since Jack's appearance on the scene, Anna becomes positively anxious to die; there is nothing in the world left for her to live for.

However dearly Alice might love her, the conditions were such that life for herself meant wretchedness for her sister. Unless her sister could be happy, she could not. If she should die, two would be perfectly happy. If she should live, three would be miserable. Her intense desire to die no doubt hastened that event, which occurred about two months after her father's death. The necessity for amputation is evident, but Alice insists on holding the corpse two days to comply with the custom of civilized people. Alice makes a quick recovery after the amputation, and her neck rapidly grows into correct relationship to her body. The outcome is a faultlessly beautiful woman, whom "to see is to love."

Her feelings after her separation from her sister, Dr. COOPER (in accordance with the well-known literary canon) leaves to the imagination, for whose assistance the fact is mentioned that the head of the sister was preserved in alcohol to be buried with Alice in the same coffin.

It must be obvious from this résumé that Dr. COOPER has excellently opened a fertile relatively unworked field of limitless possibilities in fiction. He might have instituted a rivalry between the two heads, or might, with the aid of the New York and Illinois statutes, have had a simultaneous marriage. He, however, preferred to blend the older romantic ideas with his fiction, and skilfully employed the self-sacrifice of Anna to relieve the general realistic gloom of the story. What the possibilities for sensational fiction are in this field is shown by the fact of the case reported years ago by a Brazilian physician, where a double-headed male, pyopagus fell in love with a single-headed female syndelphus with a double pair of lower extremities and two sets of pelvic organs. It is hoped, however, that future delvers in this field of fiction will emulate the delicacy of Dr. COOPER in their productions.

MEDICAL CONFIDENCES AND MEDICAL TESTIMONY.

The question of medical confidences is a perennial one, and will be till some uniform regulation or understanding is reached in regard to it. It is, moreover, not a subject that can be left exclusively to the ethical sense of our profession; it has its legal bearings entirely apart from what we may or may not consider our individual duty in regard to it, and the question may arise at any time whether as physicians we shall be compelled to state for the benefit of lawyers and their employers what we may have received as confidential communications from our own clients. As the case usually stands, and in most parts of our country, the legal has a decided advantage over the medical profession. In a few States, it is true, there are rigid statutes in this regard, that would even quench the gossip that thoughtless men have sometimes been guilty of, under penalty, but these, like most other

statutory enactments, are possibly evadable by clever lawyers, one of whom has said that he never saw a law framed that he could not drive a coach and four through. Where such laws do not exist they have a free hand, and doctors are generally at their mercy.

There is another aspect of the case, and one even less satisfactory, in the fact that there are physicians of reputable standing in the profession, whose sense of medical honor is not sufficiently high to keep them from voluntarily violating professional confidences for a fee, sometimes a pitifully small one at that. Let a case for damages against a railway company be supposed, whether meritorious or not is indifferent to the present question, the defendant corporation naturally seeks in every way to find something to break the force of the plaintiff's claim. This may often be best done by attacking his former health record, and it is not infrequently the case that physicians who have treated him prior to the injury complained of, are found willing and even anxious to go on the witness stand to reveal facts obtained by them in confidence that may be utilized in the defendant's case.

It is not a valid excuse for such a course to say that by it a fraud is prevented, for this implies an absolute knowledge of all the facts down to date, which is rarely possessed by these witnesses, and it is therefore also within the bounds of possibility that by their testimony they are assisting in an act of rank injustice. The only proper professional course would appear to a right-minded man in such an emergency to be to keep out of the case altogether and leave the medical testimony entirely to the corporation's and plaintiff's doctors and experts. Those who are authorized by the parties interested have, of course, a right to testify, but without such authorization it is difficult to characterize the conduct of a physician who reveals voluntarily what he has learned in his professional capacity, and that to his patient's damage, as anything else than dishonorable. Even the advertising specialists, who are reckoned as without the pale of legitimate medicine, have sometimes a higher ethical standard in this respect than some of the so-called regular members of our profession.

Of course there may be occasions when the rule of professional secrecy does not hold in a strictly individual moral point of view. Treason and murder, and some other exceptional conditions might be excluded, and no one would blame a physician if, for example, he should do his utmost to prevent, let us say, the marriage of an innocent female to a man rotten with syphilis or suffering from any form of actively contagious venereal disease. He might under some interpretations of the laws make himself liable for damages, as has actually been the case in France, but there marriage is looked upon more as a financial transaction than it is in this country, and courts conduct themselves accordingly. In such a case, moreover, very much may be done without actually vio-

lating medical confidence, which should be only done as a very last resort, all other means having failed. The physician should, moreover, be sure of his facts and be able to demonstrate them and the honesty of his motives before a judge and jury, as well as to convince them that he had acted with due discretion and had given no needless publicity to discreditable suspicions. The failure in these respects was undoubtedly the cause of the excessive award of damages in the celebrated PLAYFAIR case in England not long since, and a similar result might easily follow like conduct in our own country. Even without special statutes against it the physician, when he violates professional confidence to the damage of his patient, does so at a certain risk.

If such is the case in the general intercourse of man with his fellows, it certainly ought not to be the privilege of the unethical physician to voluntarily reveal the facts entrusted to him before a jury to the intended injury of his former patient, and to do this for a fee, thus dishonorably making a second profit from the confidence entrusted to him. Nor should it be the law that he can be compelled to testify or even allowed to do so in cases where he has not a personal interest involved, as in suits for remuneration or in personal defense of his property or his liberty. In all other cases his knowledge thus obtained should be privileged; professional medical confidences thus gained should be held sacred in courts of law. Where there is now no recognition of this by the courts, legislation should at the earliest possible moment supply the deficiency.

PROGNOSIS OF EPILEPSY.

Epilepsy has been studied more or less diligently for the past three thousand years. Notwithstanding this fact, we are surprised, in the review of the literature, to find how few good general rules there are for a basis of prognosis in this affection.

Since we have established colonies and special institutions for epileptics, we hope to see something done to aid the general practitioner in extricating himself from the predicament of making a prognosis in this disease.

As yet we have to learn of an institution for epileptics in which a department has been established for experimental psychology to be used for the end of a more definite study of epilepsy. When such a department shall be established in connection with these institutions, similar to those referred to by Dr. FREDERICK PETERSON in his inaugural address before the New York Neurological Society, then we shall be able to measure the exact degree of motor, sensory, sensory motor and idio-sensory and motor defects of the epileptic and ascertain to what extent the hereditary element is at fault in the epileptic predisposition. Again, we shall be able to find the state of the mental faculties, how much they have undergone impairment

in any single case. When we take into account that an insane epileptic has never yet been known to recover from his epilepsy, we at once see how important such study becomes.

We have reason to believe that the acquired impairment, mental as well as physical, may be separated in a measure, by careful observation, from hereditary impairment so often found in this disease.

Up to the present time sane epileptics have not been brought together in this country in sufficiently large numbers to warrant such thorough studies, but we hope that the Craig Colony of New York State, established at Sonyea, will speedily grasp the importance of such work in a field where comparatively little has been done. We trust that such study will be attended by success and profit to the scientific medical world.

CHOLERA BANDS FOR TROOPS.

In the early days of the Civil War the soldier from the north was not considered to be properly equipped for service in the south without a havelock or white cover of washable material for his forage cap, with a flap falling to the shoulders to protect the head and neck from the scorching sun. Ladies all over the land made these havelocks, but the troops in the field never wore them. On a hot day's march the soldiers put one or two broad green leaves, oak, maple or sycamore in the crown of his cap as an all-sufficient protection. At the present time the havelock seems to have been forgotten, and cholera bands or abdominal bandages have become the imperative necessity, to supply which, for the protection of our soldiers in Cuba and the Philippines against diarrhea and dysentery, the patriotic ladies in many of our cities have been sewing assiduously for several weeks back. It is generally understood among the profession that the flannel bandage has a reputation in tropic climates as a prophylactic for intestinal affections. Professor PARKES in his "Practical Hygiene," states in discussing the causation of diarrhea and dysentery that in almost all hot countries chilling of the abdomen is considered particularly hurtful, and shawls and waistbands are usually worn, giving as an instance the cummerbund of India; but it is difficult to understand how this knowledge became popularized so quickly, and with such practical results at the present time. Various patterns have been used. The simplest consists of an apron of flannel, six or seven inches in length, tied around the waist with tapes. Others are more elaborate, fastened with buttons, hooks and eyes or eyelet-holes and laces; but whether the men will treat them as their fathers treated the havelocks appears as yet to be unknown. The subject, however, will soon be ventilated and placed upon an official footing, for a board of medical officers has been appointed by the War Department to meet in Washington, D. C., for the purpose of considering the question as to whether

or not the Government should issue the so-called "cholera bands" for the use of United States troops in the field, the idea apparently being that if the bands are essential to the welfare of the men their supply should be furnished officially, and not be left to voluntary contribution. The board consists of Colonel DALLAS BACHE, Assistant Surgeon-General, Lieutenant-Colonel CHARLES SMART, Deputy Surgeon-General and Major WALTER REED, Surgeon.

CORRESPONDENCE.

Pottery Evidences of Leprosy.

NEW YORK, July 20, 1898.

To the Editor:—I send you a translation from the *Dermatologische Zeitschrift*, May, 1898, on Huacos pottery evidences of leprosy in pre-Columbian America, a continuation of the discussion on my paper, "The Question of Pre-Columbian Leprosy in America," and my photographs in the Berlin Lepra Conference. Dr. Glück entirely agrees with me that these Peruvian figures show no characteristics of leprosy. (*Vide* "Pre-Columbian Leprosy," JOURNAL OF AMERICAN MEDICAL ASSOCIATION, April, May and June, 1895.) Virchow, in his position, is clearly wrong. ALBERT S. ASHMEAD, M.D.

LETTER OF MR. COUNSELOR OF SANITATION AND CHIEF PHYSICIAN, DR. LEOPOLD GLÜCK, IN SERAJIVO TO THE DERMATOLOGISCHE ZEITSCHRIFT (PROF. LASSAR'S PAPER), BERLIN.

"... Mr. Polakowsky was kind enough to send me a reprint of the Berlin Anthropological Society of what Virchow says about the morbid representations on old Peruvian pottery. In the last of the communications, of Dec. 18, 1897, Mr. Polakowsky refers to my humble person, saying: 'You will find three papers about the leprosy of the nose in the first volume of the communications of the Lepra Conference. Among them there is also a great work of Dr. Glück, chief physician of the lepra hospital in Serajivo. This gentleman said to me, after the October meeting, that I had been quite correct in my judgment that these vases did not represent leprosy. He asks me to say at the next opportunity, referring to himself, that the nasal leprosy has another aspect, that the bridge of the nose sinks, that the openings of the nose are closed, that the wings of the nose swell considerably, giving the idea of a opera-glass; these are the *ipsissima verba* of Dr. Glück. Dr. Leloir, one of the first leper physicians, who died prematurely, uses the same designation.' It is correct that after the meeting of the Berlin Anthropological Society, Oct. 16, 1897, at which I assisted, on the invitation of Dr. Virchow, as a guest, I have declared to Mr. Polakowsky that these vases represent no leprosy; it is likewise true that I have spoken with the said gentleman about the deformations of the nose in lepers, but I can not remember whether I have mentioned then, only the opera-glass nose, or also the other deformities of this organ. At any rate I want to declare here that I distinguish not one, but three types of nasal deformities on leprosy, as appears from my report published in the first volume of the Transactions of the Lepra Conference: 'Leprosy of the upper respiratory and digestive tracts.'

"But it was not the defects of nose and lips alone which compelled me to believe that the vases did not represent leprosy. In considering those vases, I asked myself what form of leprosy we could have here? The faces of the fingers show no vestige of leontiasis; the tips of the ears are neither thickened nor elongated; the hands are not swollen, therefore we can exclude lepra tuberosa, especially as extensive mutilation of the inferior extremities never occurs in this form of leprosy.

It could then only be lepra nervosum sen anæsthetica. It is true, I know neither by the literature nor by personal observation any case of lepra nervosum in which the tip of the nose and of the septum, as well as the upper lip, have perished; yet this would not be impossible, especially if one considers that paralysis of many facial nerves, with consequent inflammations and ulcerations of the skin, are not particularly rare in this form of leprosy. The mutilations (?) of the legs, it is true, do not occur frequently either, in the form which is represented in our vases; but this is also possible in lepra anæsthetica. But now the hands of the figures show absolutely nothing abnormal, which alone speaks quite decidedly against the assumption of leprosy.

"It may happen here and there, now and then, that the affections on the legs are more advanced than on the hands, but it is entirely improbable that the latter, in such a later stage of disease as that represented on the figures, could remain entirely intact. The muscular atrophy and the contractions of the fingers are, in all cases of lepra nervosum which have reached any considerable degree of development, manifestations so conspicuous and characteristic, that the old Peruvian artists would certainly have been aware of them.

"Finally, as to the legs, I see in them no mutilations, but amputation-stumps, as those which remain after a regularly executed amputation of the leg. The stump has a smooth hemispherically-shaped extremity, deep, horizontal or vertical furrows, which must be considered as retracted scars after flap amputation on the legs.

"If we consider all these facts, one becomes convinced that the old Peruvian potteries which Virchow, on the 13th of October, 1897, has demonstrated in the third sitting of the Lepra Conference, and which afterward have repeatedly been the object of debate in the Berlin Anthropological Society, certainly represent no leproses.

"It must be left to the investigator of the old Peruvian civilization to explain in a positive manner the meaning of the vases in question, that is, of the figures which adorn them; the leprologist can do that only in a negative manner, by declaring that the affections which are apparent in them can certainly not be considered as leprosy."

A Department of Health.

CHICAGO, July 28, 1898.

To the Editor:—Congress adjourned, and with the knowledge presumably (see reports of Senator Gallinger and others, from personal observations made while investigating certain parts of Cuba last spring of the great need and urgent necessity of reform in sanitary matters among the unhappy people of that desolate island) or oversight, that legislation upon this all important topic was apparently either relegated to the waste-basket, pigeon-holed or deferred. Call it by whatever term we will.

For years the writer, in his feeble efforts, has tried to use what influence he possessed to promulgate argument, why our government should establish a department of health, having at its head an efficient, painstaking, scientific medical secretary. A large majority, perhaps 90 to 95 per cent., of the medical profession throughout our country have favored this project. The JOURNAL has repeatedly published the same views. The great majority, as just stated, of the noble men in our profession favor this, and as such are good samaritans (not for self aggrandizement, as possibly some might interpret, but for "the welfare of our people"), and our National legislators should have listened to our appeal, *i. e.*, paid heed to the bill prepared by the special committee of the AMERICAN MEDICAL ASSOCIATION upon this timely measure. Congress, in my opinion, will doubtless do so in due time; but, in my judgment, this much-needed legislation should have been enacted years ago. Had this been done, an intelligent commission,

composed of medical scientists from the United States, would doubtless long ago have been detailed to visit the Philippine Islands, the Canary Islands, the Ladrões, and other Spanish territory, and report upon the *status praesens* of the diseases that prevail or are indigenous to those islands, and upon the sanitary and other conditions existing among the inhabitants. A full knowledge of the sanitary conditions of Manila, Santiago, San Juan, Porto Rico, the city of Ponce, Havana, and of all other portions of those pest-ridden cities, and in the islands named, would have been officially known, not omitting, of course, Honolulu, the East Indies, etc., as well as scores of other places that might be enumerated.

This brings the writer to mention that the hardships and suffering, by illness and otherwise, of our brave soldiers at the front would doubtless have been greatly mitigated and unknown numbers of our brave sons saved from death by yellow fever, if such a branch of our Government had been established. Indeed, is not this a crying necessity? Is this not, *Jure humana et Jus divinum?* Very sincerely yours,

LISTON H. MONTGOMERY, M.D.

The Probate Court.

CHICAGO, July 30, 1898.

To the Editor:—I am glad to see Dr. Galloway has the courage to relate his experience with Judge Kohlsaatt. It probably coincides with the experience of the majority of physicians who are so unfortunate as to be obliged to prove their accounts in the probate court.

Some months ago I filed a claim against an estate in which the executrix was willing to allow the claim at \$8 a visit, and Judge Kohlsaatt arbitrarily cut the claim down to \$2 a visit, not inquiring into the circumstances of the case but remarking that the court would never allow a claim for more than \$2 a visit. I admire a judge who looks sharply after the interests of heirs, but think it is time we as physicians should take a hand in the election of the probate judges and try and secure the election of judges who will give us just fees and not humiliate us in court. Yours truly,

JOHN A. ROBISON, M.D.

PUBLIC HEALTH.

Behring's Tetanus Antitoxin has a record to date of eleven recoveries and eleven deaths, according to the *Munich Med. Woch.* of May 24.

Sanitation of Match Factories.—The recent agitation in France has resulted in the production of a sanitary match paste which contains none of the dangerous white phosphorus and is harmless alike for the workmen and the public. It is claimed that the new matches made with it are more than satisfactory.

Tubercle Bacilli can be readily detected in milk by adding a few drops of peroxid of hydrogen to a sample of the milk in a test-tube and then a few drops of paraffinlecadiamin, $C_6H_4 \cdot 2(NH_2)$. The color of the milk remains unaltered unless it contains tubercle bacilli, when it at once turns a grayish-green on being shaken.—Professor Storch: *St. Petersb. Med. Woch.*, June 11.

Doctors Opposed to Marine Hospital Extension.—John B. Corlies has run afoul of the medical fraternity. He has, in a euphemistic way, called Dr. C. Henri Leonard a liar, and the Doctor does not like it. Besides, the several medical associations think that Corlies has not acted square on their pet measure of a department of health. The agitation for such a department was started about six years ago, by the AMERICAN MEDICAL ASSOCIATION. It was proposed to make the secretary a cabinet officer, to have the Federal Government exercise control over the hygienic condition of the country and over intercourse with

other nations. President Cleveland recommended the measure in one of his messages, and the doctors have been driving at it since. During the session of the Michigan State Medical Association last May, it transpired that Corlies was pushing some health bill. It turned out to be the "Hepburn bill," which enlarges the scope of the Marine-Hospital Service. The doctors have no use for this measure, and adopted condemnatory resolutions, which were sent to Corlies. Corlies wrote back that the medical fraternity had acted without proper investigation; that it was his "duty" to report the Hepburn bill; that the bureau scheme would be a "very large expense." He trusted Dr. Leonard would "undo the evil" he had created by the publication of "facts not true." This made Leonard hot. He replied that Corlies had quibbled, and warned him that the Hepburn bill was distasteful to the entire medical fraternity. He criticised Corlies' plea about "expense" and reminds him that the doctors may conclude that some Congressmen are too "expensive." This correspondence was published in the medical journals and evoked a letter to Leonard from Dr. Wingate, chairman of the Public Health Committee of the AMERICAN MEDICAL ASSOCIATION, in which he says that Corlies obstinately favors the Hepburn bill, and that he simply would not listen to arguments for any other measure. Dr. Wingate intends to place the entire correspondence in the hands of Senator Spooner and Congressman Otjen, strong friends of the department bill. Corlies will have more explaining to do than he had with the ticket-brokers when he found himself in a somewhat similar position. — *Detroit News*, June 26.

The U. S. A. Hospital Ship "Relief."—The finest hospital ship that ever floated is the *Relief*, just fitted out at the Brooklyn Navy Yard, under the charge of Surgeon George H. Torney, U. S. A. The result is a great credit to that officer, who has given his personal attention to every detail of construction. The *Relief* was formerly the steamer *John English* (*Vide JOURNAL*, July 2 p. 42) plying between New York and Portland. There are two wards on the promenade deck, fore and aft; two on the main deck, and another on the after berth-deck. Not less than 350 patients can be accommodated in the five wards as now arranged, and by the addition of extra cots it is estimated that 500 wounded men could be cared for in an emergency. The officers' ward is forward on the main deck, and does not differ materially from the others. On the after main deck is the surgical ward, and adjoining this is a good-sized and well-lighted operating-room. In it are three operating-tables and two cabinets for surgical instruments. The entire interior of the vessel is finished in white enamel paint with gold trimmings. The floors of the wards and operating-room are covered with rubber tiling. The cots are of iron, painted white, and most of them have an upper and a lower berth, arranged like a sleeping-car section, to accommodate two patients. In each ward are baths fitted with the Gegenstrom system of hot and cold water, by means of which water may be drawn and kept at any temperature desired, by simply turning a lever above tub. The plumbing is said to be the finest ever put on board a ship. On the berth deck are staterooms to accommodate fifteen male and fifteen female nurses, and forward are the roomy and well-lighted officers' quarters. The ship carries a disinfecting plant, an ice-plant capable of producing 200 tons a day and an electric plant which supplies power for incandescent lights throughout the vessels and also for a 7000 candle-power searchlight, which is operated from the pilot-house. In addition to this all the wards and the quarters of the officers and the nurses are provided with high-power electric fans, which are expected to cool even the heated air of Cuba. A small portion of the after promenade deck has been left open at the sides, and here hammocks are to be swung for the benefit of convalescent patients. Besides the appliances already enum-

erated, the *Relief* has a carbonater for supplying mineral water, two X-ray outfits to aid the surgeons in locating bullets, a microscopic laboratory, and a well-equipped photographic dark room. On the main deck is a telephone, by means of which communication may be established with the shore or with other vessels. The ship carries eight life-boats, four life-rafts and two 28-foot steam launches. Her exterior is painted white, except for an olive-green band which will encircle the vessel, in accordance with the requirement of the Geneva convention. An apparatus has been devised by means of which the sick or wounded may be hoisted on board with the least possible trouble. This consists of a steel boom, which can be swung over the deck of a war-ship, and is fitted with tackle for hoisting.

NECROLOGY.

WILLIAM PEPPER, M.D., the friend of young men, is not now numbered among the living. He has been cut down in the height of his glory. When word came from California, whither he had gone for a brief respite from his labors, announcing news of his death from angina pectoris, it fell like a pall over the hopes and ambitions of many men in Philadelphia. His father, the elder Dr. Pepper, was one of the emi-

WILLIAM PEPPER, M.D.

nent men of his time, and therefore, by birth and by nature, his advent into the world was distinguished. Dr. William Pepper was born in Philadelphia, Aug. 22, 1843. His early life was one of progress, and his whole career one of work and usefulness. The keynote of his success was intuition, tact, persistence and constant application. No doubt he would have succeeded in any profession he might have chosen. Dr. Pepper graduated from the University of Pennsylvania when 19 years old and at the age of 23 received the degree Doctor of Medicine. From that time onward his life was devoted to utility and to the elevation of his profession. At the age of 25 he became professor of pathology of his Alma Mater and of his beloved college. In 1840 he was made professor of clinical medicine and at the age of 33 succeeded Dr. Alfred Stille as

professor of theory and practice of medicine in that institution. In 1881 he was elected provost of the University and resigned in 1894. His administration was marked by unparalleled success. If you wish to see evidences of his genius in Philadelphia "look around you." From a university of modest proportions, he built one which now covers fifty-two acres of ground, and aggregating, all told, \$5,000,000 in value. Dr. Pepper has given hundreds of thousands of dollars to the University. Under his administration there arose the Wharton School of Finance and Economy (1881), the Department of Philosophy for Post-Graduates (1882), the Department of Veterinary Medicine (1883), the School of Biology (1885), the Department of Physical Culture (1885), the School of American History (1891), the Department of Archeology and Paleontology (1891), and the Department of Hygiene (1892). He was instrumental in building the Agnew Memorial Wing to the University Hospital, the Maternity Hospital, the Wistar Institute of Anatomy, and he built and endowed the William Pepper Laboratory, a memorial to his father. His fervent hope was that the University should outrival the colleges of the old and new world. In the medical department his efforts have always succeeded, and his endowment of \$50,000 made this University one of the leading spirits among all others in requiring a four-year graded course. He brought together in this teaching faculty many of the foremost men of his day. Agnew, Leidy, Wormley and Goodell are gone, but there yet remain Wood, Ashhurst, White, Tyson, Piersol, Reichert, Penrose, Hirst and Abbott among the living. He not only gathered to this center the older men, but also looked to younger men to perpetuate it when others are gone. He gave them encouragement and they honor him for it. Always showing an intense zeal for his work, he animated others who came under his direct teaching. A man of keen perception, a wonderful judge of human nature, and of profound learning, he was bound to succeed. As a diagnostician, possibly no man was his superior. His mind was ever alert, ready to grasp the hidden thoughts of the patient and to detect the varied page of disease. He was artful to a wonderful degree and elicited symptoms which often defied the senses of others. His talents secured his reputation and his private practice was immense. As a lecturer he had few equals. His language was clear and his phrases most plain. He had a faculty of readily imparting the knowledge which his energies had brought him and they were untarnished when he imparted them to others. Dr. Pepper's talents were versatile and his great vitality gave him no rest. He was constantly reaching out for other useful fields than medicine. He was a man of executive ability, an organizer, as shown by the establishment of the Philadelphia Museum, of the School of Industrial Art, and many public enterprises. He was a leader in the American Society for the Extension of University Teaching, and always exercised an interest in all public measures which brought good to his fellow-man. Dr. Pepper's reputation was not merely local: his name is known throughout the medical world. He had been knighted by the King of Sweden and received the degree of LL.D. from both Lafayette and Princeton. As a writer he is well known. Who has not heard of Pepper's "System of Medicine, and of the "Diseases of Children" by Meigs and Pepper? A visitor to his office would always find him occupied, and this incessant toil sowed the seeds which at last broke him down. An attack of la grippe last year left its mark upon him, which a journey to Florida never relieved. His manner was kind, gentle, wholesouled, and his demeanor always suave, frank and affable. He made friends readily. His name has been honored by his native city and State, by the two Americas, being president of the first Pan-American Medical Congress, and by the Old World, and at the age of 55, lacking one month, his life work has ended. His friends are many and their grief is made the more profound since death

came when so far away from them and from the city which will do honor to the name of William Pepper for generations to come.

HENRY E. DIETRICH, M.D., 422 Center Street, Chicago, died at a private sanitarium near Milwaukee, from nervous troubles, the result of a runaway accident several years ago, July 22, aged 48 years. Dr. Dietrich had practiced here for fifteen years, was a native of Switzerland and a son-in-law of the president of the Swiss Republic, Carl Schenck. He studied in Zurich, Berne, Heidelberg, Prague and Vienna. In 1877 he came to America and went to Yankton, S. D., where he practiced until 1880, then coming to Chicago.

P. N. ADAMS, M.D., Dayton, Ohio, July 17, aged 44 years. —Robert Geddes Graydon, M.D., Southport, Ind., July 23, aged 79 years. —J. W. Gulich, M.D., Corsicana, Texas, July 23, aged 69 years. —G. B. Harrison, M.D., Washington, D. C., July 19, aged 54 years. —Charles H. Mitchell, M.D., Baltimore, aged 41 years. —George W. Patton, M.D., Pana, Ill., July 24, aged 65 years. —S. M. Swan, M.D., Johnstown, Pa., July 23, aged 68 years.

NEW INSTRUMENTS.

NON-SLIPPING PEDICLE LIGATURE.

BY W. V. GAGE, M.D.
MCCOOK, NEB.

By the use of the accompanying crude drawings, I wish to illustrate the application of a non-slipping pedicle ligature. It is impossible for it to slip from the pedicle when properly tied, a thing, I believe, which can be said of no other pedicle ligature.

The grasp of the ligature is limited, but by repeating the tying process a pedicle of any size could be securely held, or the entire broad ligament tied off. Let Fig. A 1 represent the pedicle. Through it is passed the ligature, on each end of which is threaded a needle, the projecting ends being numbered 1 and 2. No. 1 is passed entirely around the pedicle under the point of exit of No. 2 and looped into itself from below, at its own point of exit, as shown in Fig. A 2. Both ends are now drawn tight, No. 1 held snugly and No. 2 passed through the tissue, at a point about one-eighth of an inch below where No. 1 goes around the pedicle, emerging the same distance below on the other side, both ends are again drawn taut enough to control any bleeding that may be present and the ends tied. Although the description of this method of ligation may be somewhat obscure, the method of applying the ligature is simple, as you may demonstrate by using a piece of roller bandage about one-fourth of an inch through, for an imaginary pedicle, and applying the ligature yourself.

A THREADED NEEDLE-HOLDER

exhibited at the German Congress of Surgery is a perforated board with a two-inch wall along each side. The threaded

needle is passed through corresponding holes in each wall and the thread tied. Two dozen can thus be fastened and the whole sterilized at once. The needles are used in turn, cutting each knot separately, and if a needle-holder is used to insert the needle, instead of the fingers, the chances for stitch-hole infection are reduced to the minimum. Needle-holders are being used more and more abroad. A useful model is illustrated in the *Cbl. f. Chir.* of July 2. One of the handles ends in a ring that slips over the little finger, from which the pincers hang when not in use. The other handle is merely a short curved crossbar for the thumb. The jaws hold the needle slanting in the proper position.

BOOK NOTICES.

System of Diseases of the Eye, by American, British, Dutch, French, German and Spanish authors. Edited by WILLIAM F. NORRIS, A.M., M.D., and CHARLES A. OLIVER, A.M., M.D. Vol. iii. Local diseases, glaucoma, wounds and injuries, operations. Pp. 962. Philadelphia: J. B. Lippincott & Company, 1898.

The contributors to this volume are: Charles Steadman Null, M.D.; George C. Harlan, A.M., M.D.; Samuel Theobald, M.D.; Swan M. Burnett, M.D., Ph.D.; W. A. Brailey, M.D.; Sydney Stephenson, M.B.; A. Hill Griffith, M.D.; Isidor Schnabel, M.D.; Joseph Schobl, M.D.; Johann Deyl, M.D.; Priestley Smith, Esq.; Emil Gruening, M.D.; Robert L. Randolph, M.D.; Herman Knapp, M.D. The translators are Charles H. Reed, M.D., Adolf Alt, M.D., Robert Sattler, M.D. The illustrations in this work are magnificent, and the publisher has spared no expense to produce a first-class work.

A Manual of General Pathology for Students and Practitioners. By WALTER SIDNEY LAZARUS-BARLOW. Pp. 795. Philadelphia: P. Blakiston Sons & Company, 1898. [From E. H. Colgrove, Chicago Agent.] Price, \$5.00.

This is an attempt to separate general pathology from pathologic anatomy and to condense the subject of general pathology into a simple volume. The work is divided into 14 chapters, as follows: 1. Introduction. 2. Vegetable Micro-Organisms. 3 and 4. Pathology of the Circulation. 5 and 6. The Pathology of the Blood. 7 and 8. Pathology and sequelae of Inflammation. 9. Pathology of Infection. 10. Pathology of Heat Regulation. 11. Pathology of Shock and Collapse, Transfusion. 12. Pathology of Nutrition. 13. The Pathology of Various Morbid Conditions which are Characterized by Abnormalities of Secretions and Excretions. 14. The Pathology of Respiration. These chapters are followed by an appendix in which is discussed ptomain poisoning; life under aseptic conditions; fragmentation of the heart; death from certain causes, such as extensive burns; drowning; death from thirst and lightning. There is also an index of authors and a copious general index.

The work is dedicated to Joseph, Lord Lister, and was primarily intended for students as a recitation book, and for that purpose is excellent, and it will be found of great value to those practitioners who wish to keep abreast with the times in the great science of pathology.

Inflammation of the Bladder and Urinary Fever. By C. MANSELL MOULLIN. Pp. 153. Philadelphia: P. Blakiston Sons & Company, 1898. [E. H. Colgrove, Chicago Agent.] Price, \$1.50.

The author states as a reason for the publication of this book the fact that the principles of aseptic surgery seem still to stand in need of an advocate when the bladder is concerned.

The book discusses the predisposing cause of cystitis; the cause and classification of cystitis; simple and suppurative cystitis; the changes in the urine in suppurative cystitis; the organisms found in the urine in suppurative cystitis; symptoms of suppurative cystitis; urinary fever; the way in which

micro-organisms gain access to the bladder; the treatment of suppurative cystitis; cystitis due to specific organisms.

Moullin is well known through his system of surgery (which has had a wide circulation in this country) as a practitioner of ability and vast experience. The monograph under consideration is one deserving of the highest consideration. We commend the work to our readers.

A System of Practical Medicine by American Authors. Edited by ALFRED LEE LOOMIS, M.D., LL.D., and WILLIAM GILMAN THOMPSON, M.D. Vol. iv. Pp. 1120. New York and Philadelphia: Lea Bros. & Company. 1898.

The contents of this volume are: Diseases of the Peripheral Nerves; Diseases of the Spinal Cord; Diseases of the Medulla and Pons; Diseases of the Brain; Functional Nervous Disorders; Vasomotor and Trophic Disorders; Disorders of the Mind; Diseases of the Muscles, and miscellaneous subjects not specially mentioned in this and the preceding volumes.

The contributors to Volume iv are: Frederick Finley, M.D.; M. Allen Starr, M.D.; Christian A. Herter, M.D.; D. D. Stewart, M.D.; J. T. Eskridge, M.D.; F. T. Miles, M.D.; F. X. Dercum, A.M., Ph.D., M.D.; Frederick Peterson, M.D.; Charles L. Dana, M.D.; William H. Thomson, M.D.; James J. Putnam, M.D.; Charles K. Mills, M.D.; Morton Prince, M.D.; W. Gilman Thompson, M.D.; Wharton Sinkler, M.D.; James Stewart, M.D.; William B. Pritchard, M.D.; William Noyes, M.D.; Landon Carter Cray, M.D.; Pearce Bailey, M.D.; A. Jacobi, M.D.; and Warren Coleman, M.D.

This work is handsomely printed and the contributors have ably represented American medicine.

Transactions of the Academy of Stomatology. Paper. Illustrated. Pp. 83. Philadelphia: J. B. Lippincott Co. 1898.

This volume covers the period from Jan. 26, 1897, to Dec. 28, 1897, and is reprinted from the *International Dental Journal*; is well printed on excellent paper and is of value, especially to practitioners of this branch of medicine.

Studies From the Department of Pathology of the College of Physicians and Surgeons, Columbia University, New York City. Volume v, Part 2. Paper. Illustrated.

This volume of studies comprises a collection of reprints of the more important articles published by the workers in the department of pathology in this institution during the college year 1897-98. The volume is gotten up in the usual excellent style noted in Columbia University publications, and contains the following papers of interest to the medical profession: "An Experimental Study on the Therapeutic Value of Blood-letting;" "Studies of Ganglion Cells;" "Suture of the Cornea after Removal of the Lens;" "A Case of Acute Leukemia;" "Further Studies (third series) on the Gonococcus (Neisser);" "A Modification of Cullen's Method of Preparing Fresh Sections for Microscopic Work;" "On the Occurrence of Typhoid Fever without Characteristic Lesions of the Small Intestine;" "The Bactericidal Action of Lymph Taken from the Thoracic Duct of the Dog;" "On a Method of Isolating and Identifying Bacillus Typhosus, Based on a Study of Bacillus Typhosus and Members of the Colon Group in Semisolid Culture Media," and "Some Laboratory Moulds."

Seventeenth Annual Report of the State Board of Health of New York. Cloth. Pp. 620. Maps. New York and Albany: 1898.

This report is for the year 1897, contains the rules and regulations for sanitary protection of water supplies of various cities, and reports of a number of special investigations in various cities, on sanitary matters. The report is accompanied by a large number of maps, twenty-four having to do with sewer systems and sewerage disposal works.

Transactions of the Medical Society of the State of California. Cloth. Illustrated. Pp. 352. Vol. xxviii. Published by the Society.

The volume is printed on excellent paper and has to do with the twenty-eighth annual meeting held at Fresno, Cal., in April,

1898, and, besides the proceedings, contains a biography of the President, Cephas L. Bard, his annual address, and reports of various committees, as well as the committee on clinical medicine, serotherapy, medical typography, etc.

SOCIETY NEWS.

American Electro-Therapeutic Association.—The eighth annual meeting of this association will be held on Sept. 13, 14 and 15, 1898, at Buffalo, N. Y. There will be an exhibition of electric apparatus for diagnostic, therapeutic and radiographic work; a handbook of information will shortly be issued by the Committee on Arrangements. Hotel Iroquois will be the headquarters; John Gerin, M.D., secretary; Charles R. Dickson, M.D., president.

Post-Graduate Medical Schools.—At the regular meeting of the Alameda County Medical Society the following resolutions were adopted:

WHEREAS, It having come to the knowledge of this association that the post-graduate medical schools of Chicago, New York and Philadelphia are permitting the matriculation of irregular practitioners of medicine; therefore, be it

Resolved, that this association voices its denunciation of this lax practice as subversive of the distinction heretofore rightly made between regular and irregular practitioners of medicine.

As regular students have been denied advanced standing in regular student bodies, we are further

Resolved, That the permission granted them, after graduation, of matriculation in regular post-graduate schools tends to discourage the standard heretofore obtaining in our regular colleges.

Resolved, That this association point out the injustice done regular practitioners in permitting the matriculation of irregulars in post-graduate schools, as they are there drilled in practical work, in manual technique, without regard to scientific acquirements; and they are, in some instances, thus enabled to compete successfully in private practice with men who were obliged to reach a higher standard of scientific attainment before being granted diplomas, and who have not had the leisure or the money to supplement graduate with post-graduate study.

Resolved, That it is the hope of this association that this matter receive the attention of other medical societies, and of the profession in general, to the end that so strong a feeling may be formed against this abuse that the governing bodies of the offending schools may be moved to correct it.

E. J. OVEREND, M.D.,
S. H. BUTEAU, M.D.,

Committee.

Oakland, Cal., June 14, 1898.

MISCELLANY.

Recurring Tubal Pregnancy.—O. Falk reports a woman of 29 years operated on twice successfully for ruptured tubal pregnancy, one on each side.—*Munich Med. Woch.*, May 31.

"The Tonsils an Open Gate for general acute infection" is the subject of an article in the *Munich Med. Woch.*, June 7, from P. Jessen, who confirms the statements of American writers.

Professor Albert's Rule in regard to mutilating operations on either male or female: "Castrate your neighbor only as you would that others should castrate you."

A Large Primary Sarcoma in the Omentum was removed by Henricus recently from a girl of five; fatal recurrence in a few months.—*Cbl. f. Chir.*, June 2.

Botulismus Antitoxin.—Kempner has produced an antitoxin from bacilli found in the fecal matters of pigs, that protects against fatal doses of botulin derived from the bacillus botulinus.—*Ztsch. f. Hyg.*, xxvi, 3.

Intermittent Exophthalmus and Endothalmus.—A peculiar case is described in the *Deutsch Med. Woch.*, No. 24, evidently caused by varicose dilation of the vena ophthalmica, exaggerated by stooping and by the menses.

Flexion of the Uterus and its accompanying pains are attributed by Schaffer to anomalies in innervation producing convulsive contractions in the posterior wall.—*Monatsheft f. Geb. u. Gyn.*, January.

Hospital for Red Cross.—Henry M. Flagler, the Standard Oil millionaire, will, it is alleged, build a hospital at Miami, Fla., for the Red Cross, to accommodate 1,000 patients. The cost of the building will be \$40,000.

Gift to Harvard Medical School.—The late James Stevenson of Brookline, Mass., a wealthy hotel owner and real estate dealer, has promised in his will \$10,000 for the establishment of two free scholarships.

The Value of Vaginal Disinfection in childbed can only be decided when the temperature is noted every two hours. Kalmus urges the general adoption of this practice to decide this important question.—*Cbl. f. Gyn.*, No. 19.

The Tomato as a Cause of Cancer.—A N. Y. contemporary gravely publishes the statement that the tomato, eaten in any form, can not cause cancer. The doctrine of signatures explains away the difficulty and there are still extant many pathologic plates which suggest decided similitudes.

National Relief.—The National Relief Committee reports from New York City some generous contributions, among which was one by Mr. D. O. Mills of that city for \$5000, to assist in the establishment of ice-producing plants at Jacksonville, Key West, Jekyll Island and Santiago or Guantanamo Bay.

The Bacillus of Whoopingcough.—Spengler and Davos, *American Med. Surg. Bulletin*, have isolated a bacillus of whoopingcough which resembles the Pfeiffer influenza bacillus. This is probably the same organism as that of Czaplowski and Hensel (*vide JOURNAL*, Jan. 29, 1898, p. 280).

The Proportion Between the Prostate and the Testes in various vertebrates indicates that these organs partially substitute each other, as in animals with large testes the prostate was extremely small, while with small testes the prostate was exceptionally large.—Disselhorst, *Munich Med. Woch.*, May 24.

The Cure of Glaucoma by Resection of the Superior Cervical Sympathetic Ganglia is reported by Jonneeco, who has performed the operation seven times for this purpose and found the improvement marked and progressive, even in cases that had resisted iridectomy.—*Presse Méd.*, June 8.

A Small Epidemic of Meningitis Cerebrospinalis has been noted recently in Paris, occurring in scattered localities, showing no evidence of direct contagion, as the microbe is enclosed in the skull and spinal cavities. The nasal or aural passages are considered the most probable routes of infection.

Radiography in Dental Surgery has been much improved by the use of the radio condenser (*JOURNAL*, xxx, 988) and "metallic rubber." Some interesting radiographs were recently presented at the Paris Acad. de Méd., among them some that showed the fully-developed canines buried deep in the palatine arch, with no possibility of eruption.

The Resistance of Pathogenic Germs in a Fatty Vehicle to the Gastric Juice has been demonstrated by the Italians. Mixed with fat, oil or butter, typhoid, cholera, anthrax bacilli and Fraenkel's diplococci remained unaffected by fresh gastric juice indicating that they pass intact into the intestines.—*Munich Med. Woch.*, June 21.

An Instructive Case of Eclampsia is reported by Vinay, the patient apparently in the seventh month, IV-para, the eclampsia of the most severe type, child apparently dead. The patient recovered after artificial delivery followed by the injection of three liters of salt solution, with the patient kept under the influence of chloroform several hours, taking 300 grams of chloroform in all.—*Klin-therap. Woch.* June 19.

Sero-reaction and Immunity.—A communication to the Paris Académie de Méd. states that although Arabs are rarely affected by typhoid fever, examination of the blood of twenty-three subjects failed to show any sero-reaction; which is a new proof that the agglutinating power is not necessarily connected with immunity, but is an infection, or defense reaction.

Peritoneal Adhesences do not follow thermocauterizing unless there is simultaneous infection, Ten Brink asserts as the result of numerous experiments on guinea-pigs. The infection of the cauterized spot with staphylococci resulted in adhesences eight times out of nine. He is confident that these conclusions will apply also to man.—*Munich Med. Woch.*, May 31.

Psychosis Consecutive to Iodoform Treatment.—Frankenburger reports a patient of 50 years treated with iodoform-glycerin injections (6 weeks, 4, each 0.5 gram. iodoform) for a cold abscess in the thigh, which healed, but a psychosis developed, with melancholia, mania of persecutions, disturbed sight and hearing, etc., which persisted long after cessation of the injections and required removal to an institution.—*Munich Med. Woch.*, May 31.

Pain in the Bones after Extirpation of the Spleen has been observed in a recent case operated by Lucetti. The pain was intense, especially in the diaphyses of the long bones. There were no other unusual phenomena; the glands did not swell, and the pains were evidently merely the results of the sudden vicarious demands upon the blood-manufacturing bones.—*Munich Med. Woch.*, June 7; *Giorn. Intern.*

De Renzi's Treatment of Pneumonia.—Fanoni, in the *New York Medical Journal* of May 7, claims for this treatment that it increases the strength and rapidly diminishes the fever. He considers it a remedy of undoubted efficacy, as indicated in the diseases caused by Fraenkel's bacillus, namely, epidemic cerebro-spinal meningitis, pleurisy, pericarditis, peritonitis, the arthritis of pneumonia, etc.

Diphtheria of the Scrotum.—Dr. le Clerc of Brussels has observed three cases of diphtheria in which the local process was confined to the scrotum, which swelled as large as a child's head. In one case the throat was also affected. All presented the symptoms of general diphtheritic intoxication, and recovered with antitoxin and local measures, but extensive plastic operations were necessary to replace the destroyed tissues.—*Dermat. Ztschrift*, May.

Multiple Neurotic Gangrene of the Skin.—An interesting case is described by Dehio, in which any slight fright, the falling of a heavy book, the spilling of a bottle of wine on the tablecloth, or anything of the kind, was at once followed by the development of a patch of gangrene on some part of the body, hand, foot, arm, cheek, which healed in a month, more or less, leaving a deep scar; patient a well-to-do young woman, otherwise healthy.—*St. Petersb. Med. Woch.*, June 11.

A Clamp to Draw Down the Rectum in extirpations, that closes the lumen at the same time was presented at the German Congress of Surgery. Between the semicircular jaws a bullet-stopper moves up and down on a slide. This is inserted in the rectum and screwed firm, the jaws clamping together around it. The stopper can be slipped out at any moment without opening the clamp. It is illustrated in the *Cbl. f. Chir.* of July 2.

Rovsing's Study of the Infections of the Urinary Passages runs through the *Ann. des Mal. Genito-Urin.* from September to March. He does not endorse the generally accepted theory which ascribes to the bacillus coli the principal rôle in these infections, but announces the existence of a non-suppurating catarrhal affection caused by non-pyogenic, urine-decomposing microbes. Any pyogenic microbe may induce cystitis, whether inoculated in some lesion of the mucosa or arriving by metastasis, but in most cases it is due to pyogenic, urine-decompos-

ing microbes, the study of which may result in a practical sero-therapy. The bacillus coli is the most frequently encountered micro-organism in these passages, usually in the mild form of bacteriuria or, when there is lithiasis, in a slight suppurating pyelitis. In a few cases it may induce cystitis and nephritis. He even considers it possible that the antagonism between the bacillus coli and other microbes may transform malignant into benign infections. His work is based on 125 observations.

Lack of Sensibility in the Female Urogenital Organs is important from a medico-legal point of view as it renders the assertions of women in regard to therapeutic or criminal manipulations unreliable. The sense of touch and localization is very defective. Calmann reports that he packed the vagina of some patients with cotton, or with shot wrapped in cotton, to a weight of 100 grams, without any knowledge on the part of the subjects of the nature of the substances inserted. The urethra and cavum uteri are sensitive to pain, the remaining parts much less so.—*Berl. klin. Woch.*, No. 15.

Ephemeral Pneumonia.—Molteni has observed a number of cases in an epidemic of croupous pneumonia, and describes two at length in the *Gaz. d. Osp. e d. Clin.* of June 5. They commenced with a sudden severe chill lasting half an hour, with unconsciousness; temperature rose to 40.5 degrees C., respiration 44 and pulse 130, but the disease passed through all its phases, including aphasia, pulmonary edema and slight paralysis, to the crisis and commencing convalescence within twenty-four hours. The streptococcus was found with Fraenkel's diplococcus in the sputa.

Local Anesthesia is supplanting general to such an extent that the number of operations in which chloroform was used at Mikulicz's clinic has fallen from 815 to 324 during the past year. Manz reduces the pain from the ligature in Oberst's "regional cocaine anesthesia" (*vide JOURNAL*, xxx, 496, 736 and 1236), by tying a second ligature close to the first when it becomes painful and removing the latter, repeating as often as necessary. He has used this method satisfactorily for severe operations on the lower arm, but prefers a 0.5 per cent. solution. Maniewicz advocates simultaneous injection of morphin, as so much of the injected fluid escapes through the incision.

Tetanus Toxin increases the Pressure.—The increase is not proportional to the dose of toxin but is closely connected with the contractions of the muscles, as is evidenced by the fact that curare arrests it. This effect of tetanus toxin is also connected in some way with the bulbar vasomotor center, as section of the medulla in the neighborhood of the cervical enlargement likewise arrests it. The frequency of the pulse is increased, and also the excursion of the vessel. The respiration is rendered systematically slower, while the expired carbonic acid increases in progressively regular amounts. *Munich Med. Woch.*, June 7; from *Morgagni*.

Derivation of the Tetanus Bacillus.—Molinari asserts after extensive research that the tetanus germs exist normally in the soil as assumed, but are found only in the superficial layers. Oxygen and sunlight attenuate their virulence, but this is enhanced by passage through the intestines of animals (not man), which seem to be their chosen home and developing place. The pathogenic germs are therefore derived from the dung of animals, consequently are most frequent in gardens, on the street, in barns, etc., wherever animal fecal dust can penetrate, including that from rabbits, poultry, cats, etc.—*Munich Med. Woch.*, June 7.

Physicians of Olden Times.—It is said that a statute of Henry VII of England ordains that the healing art shall be limited to those persons who are profound, sad, and discreet, grandly learned and deeply studied in physic. Upon the whole, this seems a formidable curriculum even for a medical student of

the present day to face. The lecturers on "profundity," we presume, would have about as much chance of imparting knowledge to their class as the lecturers on botany have in the present century. As for the lecturer on "sadness," there would certainly be a difficulty in filling the post. Without awaking further inquiries into the adaptability of Henry VII's curriculum for the medical students of his time, we feel certain that our own is generally calculated to be in the end more useful to the community.

Bertillonage to Receive Tardy Recognition in Germany.—The Germans have been slower than others in adopting Bertillonage, as it is called, the system of personal recognition by a series of measurements and the notation and registration of any natural pigmentary or hairy peculiarities. While the system is in use in France and very generally in Belgium, Switzerland, Russia and Italy, only isolated cities in Germany have adopted it. Some recent work with it at the prison at Moabit, in Berlin, has been encouraging, and now it is announced that the police departments of most of the south German towns are about to adopt it, Munich, Nurnberg, Regensburg, Augsburg and Wurzburg having already made the necessary arrangements for its introduction.—*Phila. Medical Journal*.

Hematomyelia from Gunshot Wounds of the Spine.—Cushing (*American Journal of Medical Sciences*, June), reports cases in which the missile lodged in the centrum of a vertebra without direct injury to the chord, but producing symptoms of hemileision; both cases illustrate unusual features of a type of the Brown-Sequard paralysis, the value of the X-ray in locating the missile without operative interference, etc. There was a degeneration of the pyramidal tract, leaving paralysis in the lower extremities, and in one case involvement of ventral horn ganglia of the cervical enlargement has resulted in trophic changes with atrophy of some muscles. He concludes that paralytic symptoms which follow injuries to the cervical region are generally due to hemorrhage in the substance of the cords and that this hemorrhage is a predilection to a site in the lower part of the cervical enlargement. The hemorrhage, as a rule, occurs primarily on one side and leads to the Brown-Sequard type of paralysis. Hemorrhage also leads to cyst formations in many cases, producing symptoms quite like those of syringomyelia. Prognosis is good when uncomplicated by sepsis.

Master not Obligated to Furnish Medical Attendance.—There are authorities, such as decisions in Illinois and Indiana, holding that where there is an extreme emergency, and an injury has been received by an employe of a corporation, it is within the authority of an agent of the employer, highest in authority at the time and place where the injury occurred, to bind the company by a contract to pay a physician for services rendered to the injured servant. But the supreme court of Colorado says that it is cited to no case and finds none, where it is held to be the duty of an employer in the absence of contract, to furnish medical service and to send to a hospital a servant injured while in the service. If by analogy to the cases just referred to, it can be said that such a duty ever exists independent of contract, which it reiterates is not the law, the court goes on to say it is only in a case of great emergency, and where it is imperative to save life or prevent great harm. The mere fact that an injury was inflicted requiring medical or surgical treatment, or that the locality where it was received was remote from the place where such treatment was accessible, the court declares in *Denver & Rio Grande Railroad Company vs. Iles*, March 21, 1898, does not make it negligence on the part of the employer if the latter declines a request from the injured servant to be permitted to seek treatment, or does not obtain for the servant, or aid him in obtaining the same. The general rule deduced is that in the absence of contract, a master is not obliged to furnish medical attendance to a servant who is injured in the performance of his duty.

The Physician of Napoleon Bonaparte.—"Few students of Napoleonic history," says the *London Chronicle*, "are aware that Dr. Antommarchi, who attended upon Napoleon I during his last illness at St. Helena, is buried in the cemetery at Santiago de Cuba. He had a brother living in that island, and after the Emperor's death proceeded thither and lived at Santiago, exercising his skill as an oculist gratuitously among the poor. After his death in 1825 a public monument was erected to his memory in the local cemetery." This Francesco Antommarchi, like Napoleon, a Corsican, according to "Chambers' Encyclopedia," did not publish "Les Derniers Moments de Napoleon" until 1826. He emigrated to America about 1836 and died at San Antonio in Cuba, April 3, 1838. He seemed possessed of a disputatious turn of mind and the last quoted authority somewhat sarcastically hints that his celebrity was based entirely upon his intimacy with the great emperor during exile, at whose death he became a beneficiary to the extent of about 100,000 francs.

Professorship Not in Nature of an Office.—People vs. New York Post-Graduate Medical School and Hospital is the title of a case in which application was made for a writ of mandamus, based upon the notion that the position of a professor in the defendant college is in the nature of an office, and that it is in the province of a mandamus to reintroduce a person into that office and keep him there. But the first appellate division of the supreme court of New York pronounces this, May 6, 1898, an erroneous view, both of the professor's true position and of the office of the writ. It says that the college is a private corporation, and its professors and instructors are simply professional men appointed to serve the institution in a particular manner. They either hold contract or honorary relations with the college; but which was not clearly disclosed in this case. If the former, the court says, a professor wrongfully removed can sue for his salary, or for any other emolument to which he is entitled. If, however, the relation is honorary, its continuance or discontinuance must be mutually optional.

Times Tonsurans.—Sheffield, in the *New York Medical Journal* of May 14, presents a method by which he claims severe cases of ring-worm of the scalp can be cured within three to six weeks. He clips the hair close to the scalp and applies once a day for five successive days over the entire scalp, but more thickly over the affected spots, the following ointment:

R	Acidi carbol.	} āā	65 0
	Olei petrolei.		
	Tinct. iodini.	} āā	110 0
	Olei ricini.		
	Olei rusci (German), q. s. ad.		500 0

On the sixth day he wipes this off with a rag dipped in olive oil, again clips the hair, washes the scalp thoroughly but gently with green soap and a soft nail brush. The next day he applies the mixture as thickly as before, and repeats the whole process regularly for three or four successive weeks, depending on the severity of the case, when it is found that new hair begins to grow and no trichophyton fungi can be found in the hair microscopically. For a few days he then applies a 10 per cent. sulphur ointment and then for about two weeks as follows:

R	Resorcini	} āā	16 0
	Acidi salicyl.		
	Alcoholis		120 0
	Olei ricini, q. s. ad.		500 0

Splenectomy.—Vanverts concludes, from a study of 279 cases, including thirteen never before published, that the removal of the spleen is never in itself fatal. The circulation is not materially affected when a sound spleen is removed, but very much enlarged organs which sometimes contain as much as liters of blood, naturally affect the circulation more. He notes the fact that after ligation of the splenic vessels there is occasion-

ally a sudden violent hemorrhage through the vessels of the wound. After removal of the spleen the red corpuscles and hemoglobin decrease and the white corpuscles increase in number, but these alterations are of varying intensity and duration, from a few days to months. The mortality in 242 cases was 102, or 41.7 per cent.; splenectomy on account of injuries, 18 with 10 deaths; abscess, 4 with 1 death; cysts, 18 with 3 deaths; hypertrophy from leukemia, 29 with 26 deaths; from malaria, 79 with 23 deaths; from other causes, 94 with 38 deaths. Vanverts' thesis is a comprehensive and valuable review of the subject, according to the *Cbl. f. Chir.* of June 11. Henricius describes in the same issue a fibrosarcoma that weighed 3500 grams, starting in the capsule of the spleen, the first of the kind on record. Splenectomy was not performed. The tumor recurred even after a second extirpation, terminating fatally.

Treatment of Leprosy in the Fijl Islands.—Prof. L. Lewin has been investigating the peculiar properties of the tree with which the Fijl islanders cure leprosy, according to the accounts of the missionaries. He recommends further research in regard to what may prove a valuable acquisition to our therapeutics, administered in a less barbarous fashion. The person affected with leprosy is placed in a small hut and rubbed down with the fresh leaves of the *excoecaria agallocha*, or poison milk tree. His body is then covered with the leaves, his hands and feet tied and he is dragged to a small fire made of boughs of the tree, his head in the midst of the heavy black smoke, about fifteen inches from the floor. The friends then retire and close the door, unmoved by the cries and appeals of the victim, who is left in this smudge for several hours, when he is removed and the skin scraped, and scratched in various places deep enough to draw blood, when he is left to rest. Some die, but those that survive are cured of the leprosy. The essential points are the heat, the long-continued action of the milky sap and its melted products, and possibly the scarifications. The tree is known throughout the Pacific as very poisonous, causing blindness if any of the sap gets into the eyes. One or two drops will purge like croton oil (*Deutsche Med. Woch.*, May 26). The *Cronica Méd. de Filipinas* mentions that the natives dip strands of cotton in the sap and dry them, soaking a strand in a glass of water, which they drink when a powerful purge is desired.

Medical Examination of Plaintiff as New Question in Kentucky.

The question whether a plaintiff in an action for damages for permanent injuries to his person may be required to submit to medical examination has, as readers of the *JOURNAL* know, received considerable attention in some of the states. But the court of appeals of Kentucky says, in *Belt Electric Line Company vs. Allen*, Jan. 11, 1898, that it does not appear to have heretofore arisen in that state. And while the decisions are not entirely uniform on the subject, it thinks that the weight of authority, which it seems disposed to follow, is that such physical examination may be demanded in cases where discovery of the truth will more likely result with, than without the examination, and the ends of justice be thereby better subserved. The conclusions which the various courts and some of the text writers have reached, it takes pains to summarize as these: 1, that trial courts have the power to order surgical examination by experts of the person of a plaintiff who is seeking to recover for personal injury; 2, that the defendant has no absolute right to have an order made to that end, but that a motion therefor is addressed to the sound discretion of the court; 3, that the exercise of that discretion will be reviewed on appeal and corrected in case of abuse; 4, that the examination should be ordered and had under the direction and control of the court, whenever it fairly appears that the ends of justice require the disclosure or more certain ascertainment of facts which can only be brought to light or

fully elucidated by such an examination, and that the examination may be made without danger to the plaintiff's life or health, and without the infliction of serious pain; 5, that the refusal of a motion, when the circumstances present a reasonably clear case for examination under the rules stated, is such an abuse of the discretion lodged in the trial court as will demand a reversal of a judgment in the plaintiff's favor.

The Question of Non-bacterial Immunity has been neglected, and yet possibly the solution of many problems may be bound up in it. Why are frogs unaffected by snake poison? why is digitalis harmless for rabbits; atropin and cicuta for goats? As a contribution to the question Prof. A. Horvath of Kasan has been investigating, and confirms the peculiar immunity of the hedgehog to cantharides. He publishes a number of tests in which freshly captured hedgehogs were fed with the fresh cantharides, which were greedily eaten without the slightest disturbance except a slight, transient loss of weight, possibly to be ascribed to the confinement. Sometimes as much as 120 flies or 30 grams were taken at a time, and the animals disposed of enough cantharides during the tests to have exterminated a regiment of soldiers, without being injuriously affected in any way. The flies were found in the dejecta in minute fragments (*Deutsche Med. Woch.*, June 26). This peculiar immunity is confirmed by Professor Lewin, who also states that the animal resists the action of opium, hydrocyanic acid and alcohol very much longer than others before showing the effects of intoxication. But it succumbs to large amounts of cantharidin administered subcutaneously or per os, and cantharidin produces an inflammatory reaction in the skin, as in other animals. He also states that neither the blood nor the serum of cantharidinized hedgehogs protects other animals against the poison, which recalls the relative immunity of birds to strychnin, and the impossibility of transferring this immunity by injecting other animals with their serum. He considers it probable that the hedgehog's tissues merely possess a higher coefficient of resisting power than others.

Against Experimenting with Instruments.—The supreme court of Wisconsin has heretofore held that, in an action for personal injuries, the court may, in a proper case, at the trial, direct the plaintiff to submit to a personal examination by physicians on behalf of the defendant. But it holds, in the case of *O'Brien vs. the city of LaCrosse*, May 3, 1898, that it was not only not an abuse of discretion to refuse, but would have been an abuse of discretion to force the plaintiff to submit to an experiment with instruments under the circumstances. This was an action brought to recover damages for a personal injury sustained by reason of a plank in an alleged defective sidewalk flying up and striking the plaintiff across the abdomen, and throwing her down and permanently injuring her bladder, or muscles connected with her bladder. After submitting to one examination, by the defendant's physicians, which was full and complete, except that the plaintiff, under the advice of her physicians, refused to permit the introduction of a catheter into her bladder, for the reason that it would endanger her health, it was insisted that the court should compel her to submit to a further examination by physicians on the part of the defendant, to ascertain the exact nature of her injuries, and how long they had existed, which the trial court refused to do, and the supreme court upholds it in not doing, as above stated. The supreme court says it seems that courts differ widely as to the absolute right to a personal examination, in the absence of statute, by physicians or experts of the opposite party. Some courts deny the right altogether. Some hold that an absolute right to such examination exists at common law. Such differences of opinion, it suggests, may be accounted for in part by the difference in the circumstances under which such examinations were requested. The better opinion, it thinks, makes the right, in the absence of statute, to rest in the sound discretion of the trial court.

Yellow Journalism Rebuked.—The following letter concerning the prurient proneness to criticise the Medical Department of the Army without due regard to the facts, is self-explanatory. This JOURNAL has been fair in the matter. Its columns have been open, but it has excluded much carping criticism, but Wm. Wood and Company's medical journal has lost no opportunity to hamper the Medical Department of the Army and cripple its usefulness by publishing "yellow" articles, while the gallant medical corps are fighting the enemy in the field. This is another unfortunate exhibition of that sort of "enterprise" which has made this publisher's organ such a notorious example of all that is worst in medical journalism. It is peculiarly fitting that in the same article to which exception is taken by the Surgeon-General, a fulsome compliment is handed a sanitary officer, whose official course has been repudiated by the principal sanitary organizations of this country.

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE,
WASHINGTON, D. C., Aug. 1, 1898.

To the Editor of the *Medical Record*, New York, N. Y.:
Sir—It is a matter of great surprise to me that a leading medical journal should condemn the Medical Department of the Army, without a hearing, upon the reports of newspaper correspondents. I regret that the pressure of official duties makes it impossible for me at present to make a full reply to these strictures. I will, however, take time to state a few facts.

The number of medical officers allowed by law is inadequate in times of peace. The total number allowed is one hundred and ninety-two (192). There are at present thirteen (13) vacancies. The administration of the Surgeon-General's Office and Army Medical Museum requires six (6). Eleven (11) are on duty at medical supply depots and as chief surgeons of military departments. One (1) is at the Soldiers' Home; fifty-six (56) at general hospitals, on hospital ships and at garrisoned posts. Four (4) have been disabled during the war by sickness. Five (5) are on duty as chief surgeons of army corps. This leaves ninety-six (96) medical officers available for duty with the troops in the field. Of these, thirty-five have been appointed brigade surgeons of volunteers and are distributed among the various army corps.

This deficiency in regular medical officers has made it necessary to employ nearly three hundred contract surgeons, and more are being employed every day. Most of these doctors from civil life are doing good service and many of them are thoroughly well equipped physicians and surgeons with ample hospital experience; but it has been impossible to make a careful selection owing to the great pressure of business in the Surgeon-General's Office, and the urgency has been so great that it has not been practicable to have Examining Boards to pass upon their qualifications.

General Shafter's Army at Tampa was thoroughly well supplied with the necessary medicines, dressings, etc., for field service, but owing to insufficient transportation he left behind at Tampa his reserve medical supplies and Ambulance Corps. Every one who has read the papers knows about the difficulties encountered in landing supplies at Siboney. As is usual under such circumstances, the fighting men with their guns and the rations necessary for their subsistence were first lauded and hurried to the front. The *Relief*, loaded to her utmost capacity with medical supplies, arrived at Siboney four days after the fight at El Caney. That she was not able to get there sooner was a great disappointment to me, but was no fault of the Medical Department. I asked for a hospital ship in good time but there was unavoidable delay in securing a suitable vessel and in preparing her for service.

It has not been the expectation of the Medical Department that every wounded man would immediately receive the attention of a surgeon. No modern army makes provision for so large a number of medical officers as this would require. But attached to our Army there is a Corps of noncombatants known as the Hospital Corps, which is the organized and authorized Red Cross Corps of the Army. At the outbreak of the war we had 800 Hospital Corps men in service. At present there are more than 4000. These men wear a brassard upon the left arm bearing the Red Cross of the Geneva Convention. We have done our best to instruct them in giving first aid to the wounded, and in a majority of cases a first aid dressing properly applied by one of these men is all that is required. All of the surgeons who have come from the front have testified to the remarkable results attained from the prompt application of aseptic dressings by our Hospital Corps men and by the soldiers themselves or their comrades. The proper application of the dressings contained in the first aid packet, which is carried by every

soldier, is, under existing regulations, a matter in which every enlisted man has special instruction. For some time past this instruction has been given first by our medical officers to the company officers, and by them to the enlisted men.

My position with reference to the inadvisability of sending female nurses to our camps of instruction, or with our armies in the field, has given great offense to some members of the Red Cross Society, and it is evident that the unjust attacks made upon me and upon the Medical Department of the Army result largely from the stand I have taken in this matter. I have gladly accepted the assistance offered us in the way of delicacies for the sick, etc., and we have now a large number of trained female nurses on duty at our general hospitals, where they are giving great satisfaction, but I see no reason to change my views with reference to the sending of female nurses with our troops in the field. They are an incumbrance to an army mobilized for active operations. This objection does not apply to the sending of immune female nurses for service in our yellow fever hospitals near Santiago, and I have already sent nearly one hundred.

The first aid dressing is to be put on at or near the firing line, and the men have usually to be transported to the field hospitals on litters. In this age of aseptic and conservative surgery comparatively little operating is required, and our regular force is ample to attend to this. Moreover, we have men selected for their experience and skill to decide whether operations are necessary and to perform them. I have never objected to the surgeons and ambulances of the Red Cross Society going to the field for the purpose of rendering any necessary assistance, but, in my opinion, they should be independent as regards transportation and should not call upon the Government for assistance in getting to the field of operations. The editor of the *Medical Record* knows that when he, in company with other prominent gentlemen from New York, called upon me in my office to offer the assistance of this organization, I said that an emergency might arise in which such assistance would be most welcome, and suggested the despatch of a hospital ship to the seat of active operations. If there has been any failure to get necessary supplies to Cuba it has been because of the difficulty of securing adequate transportation and of landing supplies through the surf; but we have been constantly importuned to transport Red Cross agents and female nurses to the front. I am informed that many of these so-called nurses had never received any special training to fit them for the duties they were so eager to undertake. The National Red Cross Society should have been entirely independent of Government transportation if it expected to fulfil its proper function of affording aid to the wounded of both armies, in accordance with the terms of the Geneva Convention.

As regards the *Seneca*, I am informed by Major Torney, in charge of the Hospital Ship *Relief*, that he transferred forty-two (42) wounded men, most of whom were entirely able to take care of themselves, from the *Relief* to the *Seneca*, because at that time it was expected that our troops would storm Santiago, and that a large number of wounded would be sent to the Hospital Ship for treatment. For the same reason a certain number of convalescents were sent from the shore hospital. Two acting assistant surgeons were sent on board with a supply of the most necessary medicines and dressings. If the ship was overcrowded or inadequately supplied with water, knives and forks, etc., the Medical Department is in no way responsible.

Finally, I would say that when the medical officers now at the front return home, I expect to have full information with reference to the efficiency of the medical service in the vicinity of Santiago, and in the meantime I hope that the profession at large will not be so ready to draw inferences unfavorable to the Medical Department of the Army on the basis of reports published in the daily papers, as the editor of the *Medical Record* has been.

Very respectfully,

(Signed) GEO. M. STERNBERG,
Surgeon-General, U. S. Army.

A Heavy Rise.—The *Medical Record* says it has every belief that "Surgeon-General" W—n "will rise to his opportunities." No reason is given for this wild flight of imagination on the part of the *Record*, and the general judgment of the American Public Health Association, the AMERICAN MEDICAL ASSOCIATION, the Kentucky State Board of Health, as expressed in recent resolutions, is to the effect that a very considerable adipose dead weight will have to be removed before this picturesque person can either "rise" very high or fly very far. However, we shall watch this highly diverting and fuga-

cious performance on the part of the *Record's* heavy-weight with interest.

Hysteric Blackmail.—What was aptly described as "one of the perils of medical life," by the presiding magistrate at a London police court, is an illustration of the difficulties which sometimes beset the medical practitioner in the discharge of his duties. Mr. A., a surgeon, was brought to the court on a warrant, charged with committing a criminal assault on a Mrs. B. The solicitor who had been instructed to prosecute said that since the case had been put into his hands he had examined the witnesses for the prosecution and, in his judgment, the evidence did not support the charge. The statement of prosecutrix was not corroborated in important points. Mr. Jones, to whom Mr. A. acted as assistant, was called and he stated that he found the prosecutrix suffering from hysteria, and that Mr. A. had only done what was quite right in enforcing the administration of a soothing draught. The judge decided that Mr. A. was entirely and completely exonerated, stating that such cases frequently occurred, and expressing sympathy with any gentleman subjected to such a charge as this. A favorable ending to an unfounded charge of so serious a nature hardly compensates for the perils the medical man is exposed to in dealing with a certain class of patients, but it affords an example of the annoyance and risks which constitute one of "the dangers of medical life."

Surgical Experiences in the Late Frontier War of Northern India.—The *Indian Medical Record* gives the following interesting conclusions regarding the last important conflict in which the English have been engaged: "The surgical emergencies of the struggle were immense, and the demands on the operative skill of the Army Medical Staff were equally so. Capital operations of the severest type have been performed by the hundred on the battle-field and in the movable camps, and so perfect has been the equipment, and so harmoniously have the medical units fitted into every emergency, that there has not been a single hitch during the whole campaign. The sick and wounded have been attended to admirably, and the results of the surgical work on the field have been brilliantly successful. Every case of amputation of limbs has proved a success. Not a single septic difficulty has been found in the whole history of the campaign. These facts speak volumes to the credit of our medical staff and to their hard-working local staff, the Military Assistant Surgeons. We understand that the great French military medical expert, who was deputed to observe and to criticise the working of the British system of military medical equipment in India, and who has seen the whole scheme in active order on the frontier, has pronounced the most favorable opinions on our army medical organization. It is, he says, infinitely superior to anything else in the world. The opinion has been fully endorsed by a Japanese expert also. Unquestionably, the Army Medical Staff has fully vindicated its professional honor in such a manner as to silence the hostile and envious criticisms of the authorities at the War Office, who so grudgingly concede the pressing reforms of which this excellent service stands so much in need."

Calisson Disease at the Gouverneur Hospital, New York City.—The first symptoms of that disease resemble those of apoplexy. In one case a man came into the hospital with every symptom of having had an apoplectic stroke. He was unconscious, the pupil of his eyes were unequally distended, his respiration was stertorous. He remained unconscious for fifteen minutes and then recovered only partially. When he did recover there was anesthesia extending all through the lower half of his body. This is a symptom usually betokening spinal trouble. For short periods he became utterly unconscious. During the time he was conscious he seemed to be perfectly rational. I questioned him and found that he remembered nothing whatever that had happened since he had been attacked by the dis-

case half an hour after he left the caisson. After he died we had an autopsy, and about the only thing we gained from it was that there had been a hemorrhage into the heart muscles. The cases vary in their symptomatology. In one case a patient's right arm became absolutely rigid in such a position that the hand was bent back near the chin. Meantime his left arm was working in spasmodic convulsions that could not be controlled. The common symptom is that of intense pain at the ears. Treatment here is to administer stimulants and to induce perspiration as copiously as may be. In most cases this works very well. On the Brooklyn side, where similar work is being done, the workmen undertake to treat one another by plunging the affected man into a hot bath. It is their ignorant way of applying the same remedy that we do here; but the depressing effect of a hot bath is a danger for the men in the state in which victims of caisson disease are usually found to be when they are picked up. The theory of the disease is that the air-pressure in the caisson prevents the system from throwing off the injurious gases of the body, particularly the nitrogenous compound. The pressure prevents the various organs of the body from discharging their functions toward one another, and congestion, with the symptoms of paralysis, results. Engineer Washington A. Roebling was obliged to give up his work on the Brooklyn Bridge for a long time, because of an attack of caisson disease and that his life was endangered by it. Three hundred or more men are employed from time to time in the caissons at the foot of Delancy Street, and they have been twenty-five or thirty applications for treatment at the hospital since the work began.

Part of Physician's Account Outlawed.—A physician sued to recover for services rendered during a term of years, some of the items of his account being more than six years old, for which reason it was contended that they were barred by the New York statute of limitations. No one tried to make out that the account between the parties was a mutual, open, and current account, so that the earlier items would be carried along by the later, as is true of some classes of accounts, but the physician insisted that the account was continued by reason of certain payments made on it. But, on that point, the fourth appellate division of the supreme court of New York decides against him; *Burdick vs. Hicks*, May 7, 1898. When it was shown that the account had run for more than six years, the court says, the burden was upon the physician suing to show that the case was accepted from the statutory bar, which he failed satisfactorily to do. The legal effect of a payment upon an account which has run for more than six years (the New York limit) is that of a new promise to pay an old debt, and the promise revives the old debt. Yet such a promise should be made with a clear and explicit understanding of the true condition of the account; and, where a creditor relies upon such a payment to take an account out of the statute of limitations, it is incumbent upon him to show that the payment was made with a clear understanding on the part of the debtor that there was a balance still remaining unpaid after such payment. The fatal weakness of this case was that the evidence afforded no ground for assuming any admission on the patient's part, or for inferring a new promise made by her to pay the balance of the debt; for the reason that there was nothing to show that, at any time when payments were made, she knew that there was a balance remaining unpaid, or that there still continued an obligation or debt in favor of the physician against her.

Avian Surgery.—Some interesting observations relating to the surgical treatment of wounds by birds were recently brought before a Genevan society by Professor Fabio. The author quotes the case of the snipe, which he had often observed engaged in repairing damages. With its beak and feathers it makes a very creditable dressing, applying plasters to the bleeding wounds, and even securing a broken limb by means

of stout ligature. On one occasion he killed a snipe which had on its chest a large dressing composed of down, taken from other parts of the body and securely fixed to the wound by the coagulated blood. Twice he had brought home snipe with interwoven feathers strapped on to the side of fractures of one or other limb. The most interesting example was that of a snipe, both of whose legs he had unfortunately broken by a misdirected shot. He recovered the animal only on the following day, and he then found that the poor bird had contrived to apply dressings and a sort of splint to both limbs. In carrying out this operation some feathers had become entangled around the beak, and not being able to use its claws to get rid of them, it was almost dead from hunger when discovered. In a case recorded by M. Magner, a snipe which was observed to fly away with a broken leg, was subsequently found to have forced the fragments into a parallel position, the upper fragments reaching to the knee, and secured them there by means of a strong band of feathers and moss intermingled. The observers were particularly struck by the application of a ligature of a kind of flat-leaved grass wound round the limb, of a spiral form, and fixed by means of a sort of glue.

Louisville.

OSTEOPATHY.—A suit has just been filed against the State Board of Health, by Harry Nelson, a graduate of the "American School of Osteopathy of Kirksville, Mo.," asking that its members be restrained from pursuing him criminally, or setting on foot any criminal proceedings against him, or in any other manner interfering with or molesting him in his profession. He also asks for a writ of mandamus compelling the State Board of Health to recognize and endorse the American College of Osteopathy "to the end that his diploma therefrom may entitle him to a certificate to practice his profession." The decision will be watched for with great interest, as it is the final card played by this "school" to gain recognition at the hands of the State Board of Health. At the last session of the Legislature it was decided that the osteopaths must pass an examination before they be granted a certificate, and as just recorded in these columns only one woman presented herself upon call of the Secretary of the Board to pass the examination. The plaintiff in this case states that the school and the system in which he practices is a perfected one, and has the recognition of law in a number of States. He understands that the State Board is preparing to prosecute him under and by authority of the act on "Empiricism," which act he alleges is in violation of the bill of rights.

FINES.—The following physicians were fined in the ordinance court, \$10 each, for not having paid their physician's license: Drs. M. Thum, F. F. Berry and Miles Willett.

LOUISVILLE MEDICAL COLLEGE.—The announcement of the reorganization of this college has just been made, as follows: Dr. C. W. Kelly, Dean and Professor of Anatomy and Clinical Medicine; Dr. Geo. M. Warner, Secretary and Professor of Materia Medica and Diseases of Children; Dr. H. B. Ritter, Professor of Obstetrics and Hygiene; Dr. A. M. Cartledge, Professor of Gynecology and Abdominal Surgery; Dr. William Cheatham, Professor of Ophthalmology, Otology and Laryngology; Dr. Jno. G. Cecil, Professor of Theory and Practice of Medicine and Nervous Diseases; Dr. W. C. Dugan, Professor of Surgery and Clinical Surgery; Dr. Adolph Pfingst, Professor of Physiology and Histology; Dr. Harris Kelly, Professor of Chemistry and Toxicology; Dr. Fouché Samuels, Professor of Practice of Surgery and Operative Surgery.

HEALTH OFFICERS' REPORT.—There were 56 deaths for the past week, with 48 the corresponding week of last year. Thirty-five of these were white and 21 colored.

Philadelphia.

PROF. JOHN GUITÉRAS WILL REMAIN IN CUBA FOR THE PRESENT.—A false rumor to the effect that Dr. Guitéras was soon to return to Philadelphia has been set at rest by the statement

recently made by Senor Dominguez, who is at present making his home at Dr. Guitéras' residence in Philadelphia. Senor Dominguez said that the report had been denied by Surgeon-General Sternberg and by Dr. Guitéras. In a private letter received recently he reported the outbreak of yellow fever among the United States troops, but stated that the epidemic was very mild and that the troops of our country would not suffer much. It is well known that as a diagnostician in cases of yellow fever Dr. Guitéras has no superior, but as to executive work he has little taste or inclination for it.

NO YELLOW FEVER FOUND.—On July 20, Governor Hastings had a conference with Dr. Benjamin Lee, city health officer of Philadelphia and secretary of the State Board of Health, relative to precautionary measures in preventing the invasion of yellow fever into the State of Pennsylvania and especially through the port of Philadelphia. It is known that boats from Cuba frequently land here, and the regions around the wharves would be fertile soil for the development of this scourge. The health authorities have therefore been up and doing, and a house-to-house inspection has been or will be made. The work was divided into two sections, Medical Inspector Taylor with fifteen assistants looking after all the houses south of Market and east of Third, while Nuissance Inspector Kennedy and twenty assistants will attend to the section north of Market Street. Dr. J. Howard Taylor recently said: "We have determined to institute this investigation in order to prevent the disease getting into this city. We do not expect it here, and the precaution is taken simply as the result of many years of experience in the regulation of health matters. If a disease, no matter how easy it may be to control, gets the start of the authorities, it will reach such proportions that the ultimate result can not be conceived of; but if it is broken at the start we can so regulate it that it will not get beyond control. That is the intention with regard to yellow fever. I want to say most emphatically that we do not anticipate an outbreak, we do not even expect one case, but we will have this inspection and observe every precaution in order to insure immunity from the disease. How we are to guard against fever victims coming in by train is difficult to determine, and if the disease does get into the city it will in all probability be by means of railroads." It is stated that should a contagious disease be found the house will be quarantined, thoroughly disinfected, and the patient sent immediately to the municipal hospital.

MORTALITY STATISTICS.—For the week ending July 23, there have been reported to the Bureau of Health 523 deaths, an increase of 30 over last week and of 48 over the same period of last year; 214 deaths were in children under five years of age. The following were some of the causes: Bright's disease, 8; cholera infantum, 86; cholera morbus, 7; tuberculosis, 46; inanition, 11; marasmus, 21; sunstroke, 10; teething, 2; uremia, 7; heart disease, 3; appendicitis, 3; peritonitis, 6; cancer, 14; dysentery, 4.

INFECTIOUS DISEASES.—This week: Diphtheria, 16 deaths and 46 cases; scarlet fever, 1 death and 25 cases; typhoid fever, 6 deaths and 70 cases. Last week: Diphtheria, 14 deaths, 73 cases; scarlet fever, 27 cases; typhoid fever, 5 deaths, 50 cases.

RED CROSS AMBULANCE.—Some time ago the Red Cross Society of this city appealed to the charitably disposed for funds necessary for an ambulance and equipments for the soldiers in Cuba. The ladies of the North Broad Street Presbyterian Church became interested in the work and quickly raised the necessary amount (\$275) besides a full set of harness. Dr. De Forrest Willard was appointed by the Red Cross to receive the ambulance on July 26.

A CASE OF MEDICO-LEGAL INTEREST.—On July 4, Coligny Scheer, a lad 14 years of age, living at 2404 North Sixth Street, received a wound from the accidental discharge of a pistol. A few days later lockjaw set in, from the effects of which the patient died. At the inquest it was learned that on June 19

the patient accidentally had a nail thrust into his foot, and the facts not being plain to the coroner as to which wound gave rise to tetanus, the case has been submitted to physicians for a correct decision.

CASES OF BERIBERI.—A few days ago seven foreign sailors with beriberi arrived from Probolinggo, one of the Bermuda Isles, on the German bark *Steinbeck*. All the patients were taken to the German Hospital, where at last accounts they were doing well.

CHANGE OF ADDRESS.

Austin J. H., from 912 Walnut Street to Commerce Building, Kansas City, Mo.
 Bartholomew, H. B., from 1468 S. Pearl Street to 104 Broadway, Denver, Colo.
 Blake, J. D., from 602 S. Paca Street to 1014 W. LaFayette Avenue, Baltimore, Md.
 Bell, S. H., from Jackson Bldg. to Ferguson Bldg., Denver, Colo.
 Babcock, H. L., from Findlay to 680 Stocking Avenue, Toledo, Ohio.

THE DIAGNOSIS AND SURGICAL TREATMENT OF MALIGNANT OBSTRUCTION OF THE PYLORUS.

WITH REPORT OF THREE PYLORECTOMIES AND
FOUR GASTRO-ENTEROSTOMIES.

Presented to the Section on Surgery and Anatomy, at the Forty-ninth
Annual Meeting of the American Medical Association,
held at Denver, Colo., June 7-10, 1898.

BY J. W. MAYO, M.D.

SURGEON TO ST. MARY'S HOSPITAL, ROCHESTER, MINN.

The stomach is undoubtedly the most common seat of carcinoma. Hartley, in a recent paper on "The Etiology of Tumors" before the New York Surgical Society, says that not less than 34.97 per cent. of all carcinomata are to be found in the stomach, and points out clearly the relation between the chronic irritation to which the stomach is subjected, and the disease.

Gussenbauer and Winiwarter estimate that more than 60 per cent. of stomach cancers are at the pylorus, and according to Bull, in more than one-half of these cases, the mechanical obstruction causes death before glandular infection takes place or the infiltration of neighboring structures is far advanced.

Senn, in his monumental work on "Tumors," says that the histologic structure of cancer of this organ mimics the tubular glands, while the character of the tumor is determined by the relative amount of epithelial cells to the stroma. This is well shown by the clinical history of the case. If the cell structure is in excess, the growth is active, ulcerates early, and glandular infection occurs so quickly that the diagnosis will seldom be made in time to be of value. In this class of cases, complete gastrectomy would be the only procedure indicated, as there will seldom be marked obstructive symptoms requiring gastro-enterostomy for relief. The successful case of Schlatter is hardly sufficient to give the operation a permanent position, nor can the curetting of the growth through a gastrotomy incision, as practiced by Bernays, be greatly commended as a palliative measure.

That variety of carcinoma of the pylorus in which the stroma is in excess, quickly produces obstructive symptoms which lead to a diagnosis, and the nature of the tumor does not favor early glandular infection. These growths are often annular in form, greatly resembling the carcinomatous stricture commonly met with in the colon. Rarely the infiltration may involve the whole of the stomach, without special contraction of the pylorus, the walls being of enormous thickness and the cavity small, the latter a point of diagnostic importance, as the great thickness of the stomach wall resembles that due to pyloric obstruction with consequent dilatation. Hektoen recently exhibited two marked specimens of general gastric

cancer before the Chicago Medical Society. The large fibrous stricture of the pylorus described by Greig Smith as probably non-malignant, greatly resembles general gastric carcinosis. Sections showing malignancy are difficult to obtain in both instances. Maylard, in speaking of this variety of obstruction, says that in the latter stages glandular infection takes place and the histologic structure of the adenopathy is typically carcinomatous.

The enormous hypertrophy of the walls of the pylorus may form a distinct tumor, and these cases have usually been treated by gastro-enterostomy, particularly by Doyen.

I have met with one well-marked example of this so-called large fibrous stricture of the pylorus which had well defined limits. If these cases are malignant, pylorotomy is indicated; this was the view I took of it and acted accordingly. Clinical experience will soon demonstrate the question as to whether they are cancerous or not.

Rokitansky long ago pointed out that extension of any form of stomach cancer to the duodenum seldom took place. Sutton describes an adenoma as a rather infrequent tumor of the pylorus, which may be obstructive in its nature and possibly become malignant. Sarcoma of this region is so rare as to be a pathologic curiosity, and need not bedwell upon here.

The diagnosis of obstruction of the pylorus and resulting dilatation of the stomach is not difficult. Senn teaches us that when the fundus lies below the level of the umbilicus, there is pathologic dilatation unless gastropptosis is present. Inspection of the abdomen in marked cases will often reveal the outlines of the stomach, and if it be distended, succussion will produce splashing sounds. It is a simple expedient in the diagnosis of dilatation to pass a stomach tube and inflate the cavity with atmospheric air by means of a valve syringe, making its outlines evident, over-distension relieving itself around the tube.

The normal stomach, as shown by Haslam, is contracted, and its walls in apposition or in close contact with ingesta. The differential diagnosis as to the malignant or non-malignant character of the obstruction is often difficult and occasionally impossible without incision of the abdominal walls. The history is of the utmost importance. A long history and a slow indefinite course in the early stages is against cancer, and in the stenosis due to scar contraction, an early history of frequent painful vomiting, especially after taking food, and the other classic symptoms of previous ulceration, are often brought out.

In cancer the onset may be insidious, but is limited to a few weeks or months, rather than years. In the latter stages the vomiting of great quantities of partly digested food at intervals is indicative of the dilatation, but has little differential value as between malignant and non-malignant obstruction.

The presence or absence of a tumor has some sig-

nificance in connection with the history. In eleven cases of non-malignant obstruction, three had a well-marked tumor of the pylorus due to a thickened board-like scar, while in seven cases of cancer operated upon, in three no enlargement could be felt. A tumor with a short history, accompanied by a cachexia, which while not peculiar to cancer, is of such frequent occurrence as to be clinically called "cancerous cachexia," is of great diagnostic importance.

What shall be said as to the absence of free hydrochloric acid, or presence of lactic acid, in the differentiation? Dr. Christopher Graham has made systematic examination of such cases as have been admitted to St. Mary's Hospital for four years. In cancer, the absence of free hydrochloric acid has been the rule, but has occasionally been absent in the late stages of non-malignant obstruction. On the whole, the chemic tests have been disappointing. The presence or absence of lactic acid varied in the same case at different tests, while the iodid test for absorption and salol test for motor power added little to knowledge more reliably furnished by clinical methods in common use. The gastroscope and the gastroduodenoscope do not give encouraging results, even in the hands of their advocates. The X-ray adds little to the diagnosis, although, as shown by the cases of Meisenbach and others, it is of the greatest value if foreign bodies are contained in the stomach. After all, of what great value is the preliminary exact diagnosis in cases of marked pyloric obstruction, as, under any circumstances, surgical intervention is necessary, and the earlier it is instituted the better will be the results, and as Haslam says, it may be impossible with the growth in hand to tell a hard carcinoma from a fibrous stricture, or a beginning cancerous degeneration of the scar of former ulceration. Other things being equal, an early diagnostic incision, to be extended if feasible into therapeutic measures, should be the rule.

In seven cases of malignant disease, which I have explored, nothing further was done. In two of these cases great improvement followed, in one case lasting for a year. Tait, long ago, called attention to the good effect upon intra-abdominal malignant disease the mere incision of the peritoneum occasionally had.

Upon opening the abdomen the cancerous nature of the disease can usually be readily recognized by the enlarged tortuous vessels in the peritoneal covering, so different from the whitish scars of former ulceration. The nature of the so-called large fibrous stricture, upon which Loretta first performed his operation of digital divulsion is in doubt. Whether the exploration shall end as such or be converted into the first step of a pylorotomy or of a gastro-enterostomy, will depend upon the extent and character of the disease, the adhesions to surrounding viscera, and the condition of the glands.

The non-operative treatment consists of careful regulation of the diet and the use of bismuth, salol and gastro-intestinal antiseptics of this class to relieve the attendant catarrh. The late Dr. David Collins of Minnesota thought the internal administration of one grain of methyl blue, with three grains of powdered nutmeg after eating, was of great benefit. Ochsner, in hopeless cases, practices the routine use of the stomach tube twice a day for the removal of the unabsorbed remains of ingesta to prevent irritation.

There are but two operative procedures which can claim serious attention: pylorotomy, a radical opera-

tion based on the hope of a cure, and gastro-enterostomy, for palliative purposes.

Pylorotomy is not a popular operation, its great immediate mortality, 40 to 70 per cent., and the few cases which have survived the three-year time limit have been discouraging, but if it is a fact that 50 per cent. of pyloric obstruction cases die before systemic infection takes place, an early operation should give better results. Bernay takes the view that the operation is useless unless we take out the entire stomach, seeming to class it with cancer of the breast or uterus, yet in cancer of the colon, which appears often as a stricture and produces an obstruction, mechanical in its nature, he would hardly hold the analogy complete and advise the removal of the entire large bowel.

When the whole question is opened it would seem that the enormous mortality has really been the objection, and the only cases which have appeared to justify the risk, have passed beyond cure. Improvements in technique will soon remove much of this fear. Kocker has had seven recoveries out of nine cases; Pean eight recoveries out of twelve cases. One cause of the great mortality in the so-called Billroth method was imperfect union and resulting leakage at the suture angle, that is, at the point where the narrowed stomach was fitted to the duodenum.

The performance of pylorotomy, and either side to end gastroduodenostomy or side to side gastrojejunostomy has remedied this weak point in the older technique and is now usually employed by the continental surgeons. Of these two later methods, gastroduodenostomy is the operation of choice, as one of the constant dangers of gastrojejunostomy is the so-called regurgitant vomiting, the bile and the pancreatic juices passing into the stomach through the fistulas opening, rather than along the intestinal tract. I quote in full from a paper which I read before the Minnesota Academy of Medicine, Feb. 2, 1898, and published in the *Medical Record* for June 11, 1898, a description of an operation for removing the pylorus and part of the stomach, which has been successfully employed by myself and my brother, Dr. C. H. Mayo, on three occasions.

These cases all recovered from the operation, and while now in good condition, sufficient time has not elapsed to speak of them as cured. The method of pylorotomy we have followed has been so speedy and satisfactory that I would like to call your attention to it. The ease with which any desired amount of stomach can be excised is especially noticeable; in one case the upper suture angle lying behind the left costal arch in close proximity to the cardiac orifice, passing obliquely downward and to the right more than six inches in length, making a sort of shovel nose to the amputated end.

I make no claim to originality, although I know of no method of equal simplicity, and in the cases referred to, and also in a number of cadaver operations, the details were readily carried out. The steps are as follows:

1. A median incision above the umbilicus and, if needed, a cross-cut of the rectus.

2. Double ligation and division of the necessary amount of gastrohepatic omentum; this allows the pylorus and lesser curvature to be delivered. The fingers are now in the lesser cavity of the peritoneum and at once slip under the pylorus and act as a guide to the careful double ligation and division of the gastrocolic omentum attached to the malignant area.

3. The diseased part is isolated by a piece of gauze drawn under it and a pair of forceps are caught from each side, separating the diseased from the healthy stomach and also preventing leakage from below. With a knife make a circular cut completely around the healthy portion of the stomach to the mucous coat. The muscular and peritoneal coats are stripped back and a few bleeding points caught with forceps. The mucous coat is cut inch by inch and at once closed by a continuous catgut suture; this is cut short and the detached pylorus and tumor is covered and turned out of the way. A second continuous catgut suture of the muscular coat rolls in the mucous, while outside of this, a good silk Lembert of the peritoneum and muscular coats protects and rolls in the two first rows of sutures.

4. The end of the stomach is slipped to the right and the ends of the tied omentum are sutured to each other and to the suture line, not only making further protection, but also anchoring the stomach to the right and preventing undue traction upon the duodenum after it is fastened in place.

5. The duodenum is cleanly amputated at a healthy point and buttoned with a Murphy button to the anterior lower wall of the stomach (at least three inches from the suture line, see Case 3).

We have made this operation once in forty-five minutes, once in one hour and five minutes, once in one hour and twenty-five minutes. I mean by this, from the time the operation is commenced until the dressings are in place, and in each case from four to six and one-half inches of the stomach have been excised.

In the appendix to this paper will be found the detailed histories of these cases. The operation herein described is a modification of the one published by Murphy in the London *Lancet* in 1895, and to him is due the credit of first clearly directing attention to the value of the combined operation.

Gastro-enterostomy, or the operation of Woltier, is a much more popular procedure than pylorotomy, although in performing it we frankly accept the inevitable. This operation has been so thoroughly discussed recently by Willy Meyer in the *Annals of Surgery* for July, 1897, and by Dr. Robert Weir in the *Medical Record* for April 16, 1898, that I will not take up much of your valuable time with it.

At present there are but two methods of gastro-enterostomy which have a considerable following: the suture operation and that with the Murphy button. I recently had the privilege of witnessing the distinguished surgeon, Professor Senn, do the suture operation. In his hands it seemed easy and was certainly rapid and satisfactory. I have made ten gastro-enterostomies, four only for malignant disease, with one death. All of my operations have been with the Murphy button, and I have had no cases of regurgitant vomiting nor of recontraction. One non-malignant case now of over three years' standing.

The collection of cases reported by Meyer and Weir show the great frequency and fatal character of the regurgitant vomit, and the importance of the subject is shown by the numerous methods of preventing its occurrence by Kocher, Doyen, Braun and others. From a careful study of histories of the fatal cases in which this has happened, I believe it to be less common with the button than with the suture. The method of gastrojejunostomy I have followed has been to grasp the jejunum at its origin and form a

coil which shall be sufficiently free to attach to the anterior wall of the stomach without dragging, using no sutures whatever.

As the stomach wall is very thick, it should be cut to the mucous coat before the puckering string for the button is put in, and the bite of the suture in the stomach wall should not be great, to prevent the button remaining too long in place. It occasionally happens that the button will drop back into the stomach. In the reported cases of this accident it has caused no harm and not infrequently it has been voided weeks or months after the patient has passed out of observation.

I think too much importance has been attached to the question of whether the bowel shall be fixed to the anterior or posterior wall of the stomach; the results seems to be about the same in either case. At the present time I believe the results, both immediate and remote, with the button are better than with the suture.

A few words in regard to the preparation of the case for operation upon the stomach. It has been my experience that the preliminary cleansing and emptying has been less perfect than would appear reasonable to expect, and at the operation a stomach apparently empty before will be found to contain a considerable amount of material, and as this viscus is elevated outside of the abdominal incision during the operation this fluid may gravitate into the dependent esophagus and be aspirated into the lungs, causing a fatal septic pneumonia. Great care on the part of the anesthetizer is necessary in these cases to prevent this accident.

Case 1. Cancer of the pylorus; pylorotomy and gastroduodenostomy.—B. McD., female, aged 61 years; Irish; admitted to St. Mary's Hospital, Rochester, Minn., Sept. 22, 1897, giving a history of an obscure stomach difficulty which had existed for several years past. Within the previous six months the character of the distress had changed, was accompanied by vomiting at irregular intervals of large quantities of decomposed food. There had been twenty-five pounds loss of weight. Physical examination.—Patient somewhat emaciated, no tumor could be discovered; stomach greatly dilated; no free hydrochloric acid. Operation Oct. 1, 1897. A carcinomatous contraction of the pylorus was found, no glandular enlargement. Pylorotomy and gastroduodenostomy. Button passed on the seventeenth day. Discharged Nov. 30, 1897.

Case 2. Cancer of the pylorus; pylorotomy, partial gastrectomy and gastroduodenostomy.—P. D., female, aged 54 years; Irish; admitted to St. Mary's Hospital, Rochester, Minn., Nov. 8, 1897, with a history of gastric symptoms extending over a period of several months. For the past two months she has vomited large quantities of partially digested or decomposing food, once or twice in twenty-four hours and has grown weaker, with a loss of about fifty pounds in weight. Physical examination.—Patient emaciated, face drawn and haggard in appearance; lungs and heart in good condition; urine contains one-fourth of one per cent. of albumin, no casts. A large quantity of decomposing food material was removed with the stomach tube; through the tube the stomach was distended with air and its lower border shown to be three inches below the umbilicus. An obscure tumor could be felt in the epigastrium; no free hydrochloric acid present in the stomach contents. Operation Nov. 25, 1897. A carcinomatous stricture of the pylorus was found, the infiltration extending along the lesser curvature to a point three inches from the cardiac orifice. No apparent glandular enlargement. Pylorotomy, partial gastrectomy (one-third of the stomach) and gastroduodenostomy. Button passed on the sixteenth day. Discharged Dec. 23, 1897.

Case 3. Cancer of the pylorus; pylorotomy and gastroduodenostomy.—M. T., male, aged 42 years, German; admitted to St. Mary's Hospital Jan. 3, 1898, with a history of gradually increasing stomach trouble during the past three years. He has been unable to eat solid food for nine months, vomiting the greater part of the nourishment taken at irregular intervals, and within a month has had two attacks of apparent complete pyloric obstruction, each lasting three or four days and accompanied by great prostration. Physical examination.—Patient

extremely emaciated, no tumor, stomach enormously dilated and partly full, the lower border apparently resting on the pelvic brim; no free hydrochloric acid. Operation Jan. 5, 1898. The so-called large fibrous hypertrophy of the pylorus was found. Obstruction almost complete. Pylorotomy and gastroduodenostomy. It was noted after the anastomosis was effected that the opening was rather too close to the suture line, but as the patient was in bad condition it was not corrected. Button passed on the twenty-first day. Patient discharged Jan. 31, 1898. Six weeks later, having up to that time gained thirty-two pounds in weight, patient was suddenly seized with symptoms of acute pyloric obstruction. His condition rapidly became worse, and in three weeks the man was reduced to a remarkable degree, the emaciation being beyond anything I have seen. As he was unable to return to the hospital, I proceeded to his home at Kasson, Minn., where I found him confined to his bed and partly delirious from starvation. With the help of my brother, Dr. C. H. Mayo and Drs. Bedient and VanCleve of Kasson I made a gastrojunoostomy. No attempt was made to ascertain the cause of the recent obstruction on account of his weak condition. For two weeks following the patient remained in a precarious condition, from which time his recovery was rapid, and in two months he had gained forty-two pounds and is now apparently well and of greater weight than ever before.

Case 4. Cancer of the pylorus; gastro-enterostomy.—A. A., male, aged 70 years, Norwegian; admitted to St. Mary's Hospital Aug. 2, 1894. Gastrojunoostomy for malignant pyloric obstruction. Death on the fourteenth day from aspiration pneumonia. Postmortem showed union complete; button in the stomach. Case reported in *Annals of Surgery* for 1895.

Case 5. Cancer of the pylorus; gastro-enterostomy.—J. K., male, aged 58 years, German; admitted to St. Mary's Hospital March 5, 1895. Gastrojunoostomy for malignant pyloric obstruction March 8, 1895. Button passed on the twentieth day. Discharged April 5, 1895. Remained in good health for thirteen months, then died from rapid return of disease.

Case 6. Cancer of the pylorus; gastro-enterostomy.—D. D., male, aged 60 years, Welsh; admitted to St. Mary's Hospital June 30, 1896. Gastrojunoostomy July 2, 1896, for obstructive cancer of the pylorus. Button passed the eleventh day. Discharged July 18, 1896. Lived for more than one year in comparative comfort before death from extension of the disease.

Case 7. Cancer of the pylorus; gastro-enterostomy.—M. T., male, aged 42 years, German; Feb. 26, 1898. Gastrojunoostomy for acute pyloric obstruction six weeks after pylorotomy for malignant disease (see Case 3). Button not passed, so far as is known. Patient now, three months after, has gained fifty-two pounds in weight and is in fine condition.

DISCUSSION.

Dr. J. B. MURPHY of Chicago—I have been much pleased with the emphasis laid by the essayist upon the importance of early exploratory operation in these cases and consider this one of the most important points in the paper. I would like to compliment the author upon the energetic manner with which he has pursued his ideas. I have made a number of exploratory operations in order to determine the diagnosis. If we are to have good results and permanent cures, which I believe we should have just as in cases of removal of the cervix for carcinoma, in the early stage, it is proper to make an early exploratory incision for the exposure and examination of the pylorus, a procedure involving a risk of less than 1 per cent. When one considers the number of cases that occur every day in practice, we are justified in taking these chances, and the time will come when we are obligated to make an exploratory incision and not allow the large number of cases of malignant stenosis of the pylorus to go on to a fatal termination as we do now. The method of drawing forward the pylorus is important, and enables us to bring it immediately out of the abdomen, and facilitates the operation. Gastro-enterostomy has become a well-recognized procedure and has much to recommend it. When a surgeon performs this operation he has rarely seen the case from the beginning, and when a medical man refers the case to the surgeon for gastro-enterostomy the patient has usually been allowed to pass beyond the line of the preservation of his life and is sent to the surgeon for operation so that he may die easy. If you let carcinoma of the cervix go on a certain time hysterectomy will be useless. In the pylorus, however, a longer time usually elapses after operation before secondary infection occurs. It makes the obligation to operate greater, because the symptoms exist for a more prolonged period and we should not be compelled to do gastro-enterostomy at such late days.

Dr. McARTHUR of Chicago—We might reverse the method

in making a gastro-enterostomy prior to the removal of the carcinomatous or constricted pylorus. If a passage were to be provided prior to the removal of the pylorus, the patient could better stand an operation later for the removal of the stomach.

Dr. JOHN B. HAMILTON of Chicago—Three years ago a case came under my observation, when I acted from similar motives to those contained in Dr. Mayo's suggestion, and the patient is still living. She was at that time 30 years of age, had vomiting, was greatly emaciated, weighed only about ninety pounds and could retain nothing in the stomach. Malignant disease of the pylorus was suspected, but no hemorrhage was present; an exploratory incision was made. When I opened the abdomen I found no glandular involvement, but there was great enlargement of the duodenum at the pylorus. I opened the stomach and passed my finger into the pylorus and examined it. I found that it yielded to the finger pressure and then inserted one, two and three fingers so as to forcibly dilate it, thus performing Loretta's operation. Finding that I now had a free opening and believing the case to be non-malignant I closed the stomach wound in the ordinary way. The woman today weighs about one hundred and forty pounds.

INTESTINAL ANASTOMOSIS BY A NEW METHOD.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY WILLIAM F. METCALF, M.D.

DETROIT, MICH.

Since Lembert, about 1825, asserted that the union of serous surfaces was to be aimed at in intestinal anastomosis, many methods of suturing have been introduced and many mechanical substances used to facilitate the suturing, but no appliance has yet been invented in the use of which the union should not be fortified by suture. This being true, if device is to be used, it should possess the following qualifications: 1, it should be rigid so as to hold the parts firmly in apposition; 2, it should, as soon as its function is performed, as soon as the suturing is done, pass quickly away to leave the lumen of the gut free; 3, it should be easy of introduction.

In gastrectomies upon dogs I found it difficult to make a satisfactory union between the intestine and esophagus. This led me to experiment with various appliances to facilitate suturing. When I decided to use sugar I had cylinders of hard candy prepared around which I filed grooves. This made them easily broken at the line of filing. To overcome this objection I had molds prepared in which to run the sugar. Many different sizes being needed, a consideration of expense led me to adopt the following method of preparation.

Cylinders of sugar are prepared carefully so as to exclude the presence of air spaces. These cylinders vary in size by the eighth of an inch, the smallest being one-half inch in diameter. By the aid of a file they are broken into pieces, one and one-half inches long. Around the center of each piece a groove is burned by a screwdriver one-eighth of an inch wide. The ends are rendered cone-shaped by the same instrument and smoothed by moistened fingers. They are then dried and wrapped in oiled paper to keep them from long exposure to the air. This device enabled me to make the union of the intestine and esophagus in less time and more satisfactorily than was possible by either the bone or metal buttons, or by unaided suturing. I then began its use in intestinal anastomoses with results that were satisfactory except for the fact that numerous adhesions would occur between the line of union and mesentery, liver, parietal peritoneum and other loops of intestine. The first four

specimens presented are samples of these adhesions. Baum's recommendation to apply to the line of union absorbable tissue is obviously wrong. I proved this to my own satisfaction, however, by careful experimentation with the application of gold-beaters' skin and the fibrous coats of stomachs and bladders. In all cases operated upon by various methods the autopsies showed one condition ever present, that the omentum became adherent to every accessible point of wounded tissue. This observation led me to direct the efforts of nature by wrapping a fold of the omentum around the gut at the point of union. This I found prevented

Figure 1.

adhesion in nearly every case, as the remaining specimens show. I knew at the time that Dr. Senn recommended the use of omental grafts and afterward learned that Dr. Theodore A. McGraw had protected his line of suture in the large intestine by covering it with a fold of omentum. Leaving the blood supply of the omentum undisturbed I consider a valuable feature of the method.

Figure 2.—A Catgut draw suture.

Figure 2 B. One end of button in place.

I will now call your attention to the method of applying the sugar approximator. (Fig. 1.) In end-to-end anastomosis, a spiral suture of carbolized catgut is passed as shown in A of Fig. 2 to bring the edges of all the coats of the gut together to the bottom of the groove shown in B. The size of the approximator

should be such that its insertion will necessitate a slight stretching of the gut. To do this without crushing the tissues, I have had made the forceps as shown in Fig. 3. Their importance is enhanced by the fact that temporary spasmodic stricture occurs near the line of section. Insertion of the other end into the gut is made in the same manner, the spiral suture tied, when the ends will appear in apposition as in Fig. 4. The groove should be shallow, to permit the placing of the first line of suture as near the edge of the serous coat as possible. I use fine braided silk. The next suture is placed in the same manner

Figure 3.—Forceps.

and about one-sixteenth of an inch from the first, the gut slipping easily over the cylinder to permit accurate co-aptation. Fig. 5 represents a longitudinal section showing sutures tightened and approximator in place. Fig. 4, omitting the red line of suture, presents the appearance of the completed union.

Figure 4.—Ends approximated, showing placing of first suture.

The subsequent narrowing of the lumen of the gut depends upon the extent of union of the serous surfaces, the extent of this union governing the amount of fibrous tissue formed, to which the subsequent contraction is due. In order to show you the extent of contraction in any case, it would be necessary to permit the animal to live several months and present a

Figure 5.

photograph of a microscopic section. This, time would not permit me to do on this occasion. Specimen No. 9 is one showing lines of suture too far apart, that is, the union of too great an extent of serous surfaces. The operation is completed by wrapping a fold of omentum around the line of union and secur-

ing it by one stitch at the mesenteric border. Lateral anastomosis may be done in substantially the same manner.

The advantages of the method are: 1, the approximator will quickly disappear and will therefore give no future anxiety; 2, with the approximator in place the mesentery may be accurately adjusted by rotating before suturing; 3, the ease and rapidity with which the union can be effected (Specimen 8 shows one removed from a dog upon which I operated without assistance); 4, the ease, rapidity and cheapness of manufacture of the approximator; 5, the spiral catgut stitch uniting the edges of the coats, tends to prevent accumulation of fluid and formation of abscess beneath the mucous coat; 6, a doctor of average surgical ability can perform the operation when emergency demands.

DISCUSSION.

Dr. H. H. GRANT of Louisville—I have done several of these operation both anatomically and surgically, and have gotten along as well without artificial aid as with it. The device suggested is a slight modification of the one we are familiar with, merely using a potato or turnip and preparing it just before the operation. The device facilitates the operation in the hands of those who have had little experience in the handling of the needle but the time occupied is not much less than a skilled operator would employ without much aid. If we must use a mechanical device we should employ the Murphy button. It is true that failure has occasionally resulted from imperfect approximation of the surfaces with the Murphy button, but this results largely from a want of familiarity with the mechanism of the button. If the serous surfaces are brought accurately together, the necessity for the use of sutures will rarely occur. The employment of these devices takes time and adds to the risk of hemorrhage. There is very little to do in securing apposition of the surfaces other than that which nature will take care of, and I question whether it will be to the interest of the profession to substitute anything for the Murphy button which can usually be dispensed with.

Dr. METCALF, in closing: I agree with the gentleman who has discussed my paper that it is an easy thing to do an intestinal anastomosis, but it is not easy at times to make the anastomoses that we are called upon to do. My experience is that I can do the operation in one-half the time that I used to be able to do it, and in such a way that there will be less serous surface to approximate. The results will be more accurate and the subsequent contraction less."

THE ADVANTAGES OF A PERMANENT ABDOMINAL ANUS AND OF TOTAL CLOSURE OF THE SACRAL END OF THE RECTUM, IN OPERATIONS FOR CANCER OF THE RECTUM.

Presented to the Section of Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY W. W. KEEN, M.D.,

PROF. PRINCIPLES OF SURGERY AND OF CLINICAL SURGERY,
JEFFERSON MEDICAL COLLEGE,
PHILADELPHIA.

In the *Therapeutic Gazette* for May, 1897, I published fifteen cases of amputation of the rectum by Kraske's method, to which I have since added two more, making seventeen in all. Three of the patients died, giving a mortality of 17.07 per cent. Of the fourteen cases that have recovered, six have now passed beyond the three-year limit and may be considered reasonably safe from recurrence. Two of the men, in spite of the loss of the coccyx and part of the sacrum, ride bicycles with ease. Besides these the paper included a number of other cases of cancer of the rectum, operated on by other methods.

As a result of my experience in these cases, I have

reached a definite conclusion as to what is the best course to pursue. Evidently after the operation the bowel must continue to be emptied of its contents. There are only three ways in which this can be done. First, in those rather rare cases in which the sphincter can be preserved and the lower end of the bowel sutured to the upper, *i. e.*, a resection rather than an amputation of the rectum we restore the natural function of the bowel through the normal anus. Second, if the anus and sphincter have had to be removed, we can suture the sacral end of the rectum at the end of the resected sacrum, pass it through the gluteal fibers and make an artificial sphincter, or rotate it to such an extent as to make a sort of supplementary sphincter. I have not tried bringing the end of the rectum out through the fibers of the gluteus maximus muscle. Both of the other methods I have tried, but

Figure 1.—The inguinal anus in Case 1.

neither has proved satisfactory. Rotation of the bowel has been followed by infection in the folds of the rectum and not very satisfactory results as to retention of feces. The sacral anus has not been satisfactory, first because it necessitates the patient's wearing for the remainder of his life, day and night, a napkin, partly on account of the constant escape of mucus, and partly on account of the want of control of the feces. In addition to this, there has always followed a greater or less prolapse of the bowel, which in some cases even reached six inches. No perineal napkin can be worn tight enough to produce pressure sufficient to prevent either of these annoyances.

Besides the annoyance of wearing a napkin, the involuntary escape of mucus and feces and prolapse of the bowel, the sacral anus has another danger at

the time of operation and afterward, namely, infection of the wound. This infection is due partly to the fact that the bowel can not be suitably evacuated, nor can it be disinfected before the operation by means of the natural anus. The cancer forms such an obstruction that neither can the feces escape downward, nor can satisfactory cleansing of the bowel be accomplished by means of enemata. After the operation also the danger of infection from the escaping feces is a constant menace to the success of the operation. I have therefore in my later operations always made a preliminary colostomy by Maydl's method. At the end of about a week, I have excised all of the protruding portion of the bowel, leaving a permanent artificial anus. The advantages of this are, first, that before the operation one can empty the upper bowel completely, and disinfect the lower bowel partly through the natural and partly through the artificial

Figure 2.—Showing the preliminary colostomy and the complete closure of the rectum after amputation.

anus. In the paper already alluded to, I have shown the impossibility of disinfecting or even of unloading the bowel prior to amputation of the rectum, even after days or weeks of effort. Secondly, an abdominal artificial anus is very much more under control, and can be cleansed very much better than a sacral anus. One can wear a belt or girdle as tight as is necessary, both to prevent undue protrusion and to prevent the escape of the feces. Figure 1 shows the result in one of my recent cases. Prolapse is present to a slight degree, but does not annoy the patient. He is a blacksmith and does his work perfectly well. Most of the cases with such an artificial anus have the bowel emptied spontaneously, once, or more commonly twice, a day, and at almost as regular hours as by the normal rectum. Of course when there is diarrhea no control over the evacuation remains, but as I have shown in my previous paper, by means of a suitable dressing, the contents of the colon, as they

escape, are caught and are prevented from becoming a source of annoyance to the patient or those about him.

In the last two cases upon which I have operated, I have taken a further step which I think is a distinct improvement in rectal surgery, namely: after amputation of the rectum, I have completely closed the sacral end of the rectum, just as one closes the end of the intestine before making a lateral anastomosis (Figure 2). The first advantage of this is that if the closure is a success, neither fecal matter nor infected mucus can reach the wound, and we are much more likely to obtain primary union, which greatly lessens the danger of life. Secondly, as the perineal wound is entirely closed, no escape of either feces or mucus occurs after recovery and the patient is relieved of the necessity of wearing a napkin. Thirdly, for the same reasons, we avoid any prolapse.

I have carried out this plan in two cases. I was not able to avoid infection, because in the first cases there was slight leakage, and in the second there was an unavoidable dead space left at the end of the

Figure 3.—Complete closure of the perineum without any sacral anus after amputation of the rectum.

sacrum, and a slight reactionary hemorrhage. But both of these cases suffered far less from febrile reaction than I have seen after the more severe infection by ordinary methods; and both have made excellent recoveries. The second case is too recent to express an opinion as to the functional results. These, in the first case, could not be better. Seven months have passed since this operation and his physician, Dr. Bashore of Bachmansville, Pa., has recently written me that the patient is working hard at his trade as a blacksmith, and can shoe as many as six horses in a day. When one remembers that in shoeing horses a blacksmith bends far over and almost constantly, one can see the great advantage that this man has in being free from the discharge and the prolapse of a sacral anus, and the necessity of wearing a napkin. Figure 3 shows the present condition of his perineum.

I would like also to call attention to the ease with which in case 2 the upper and lower colon were exam-

ined by Kelly's tube from the artificial anus as far as the sigmoid and the transverse colon. In doubtful cases, as this was, the method will prove of great use in determining whether any operation should be done.

A brief account of these cases is as follows:

Case 1.—Mr. H. H., age 55. Has had bloody passages from the rectum for three years, and has lost 29 pounds in weight, although still weighing 175 lbs. A thick, nodular mass entirely surrounds the rectum; no adhesions. Nov. 3, 1897, preliminary colostomy, Maydl's method. Bowel opened on second day, and entire protruding portion cut off flush with the abdominal wall at the end of a week. Disinfection of the lower bowel by boric acid through the natural and the artificial anus. Nov. 17, resection of rectum and coccyx, and sacrum removed to 3rd sacral foramen: 13 cm. (5 in.) of the bowel amputated, without opening the peritoneum, but exposing the prostate, vesiculae seminales, and a large part of posterior wall of bladder (Fig. 4). Fifty ligatures. Invagination and closure by Lembert sutures of lower end of rectum. Closure of perineal wound. On the fifth day, probably as a result of slight leakage, temperature 103 degrees. Small amount of pus evacuated, when temperature immediately fell. Out of bed on 18th day, and went home a few days after. Dr.

Figure 4.—Specimens removed in Case 1. Rectum, coccyx and part of sacrum.

Bashore writes: "The artificial anus answers admirably and has no disadvantages whatever. The mucus that collects in the rectum and lower colon is expelled upward. In the patient's own words: 'I feel as I formerly felt before stool; then, on bending forward, a sensation as if I had a stool, and the mucus is expelled on the bandage.' This happens about once in two days. He is in splendid physical health and has resumed active work as a blacksmith."

Case 2.—E. T., age 50. Pain in the rectum for a year and a half, with occasional blood. Was admitted to the Jefferson Hospital Dec. 20, 1897. A week before his admission I had examined the rectum in the out-patient department, by Kelly's proctoscopic tubes, and found a number of small polypi. Three of these were twisted off and examined by Prof. Coplin, who reported that they were tubulated adenomata, which in a patient of his age usually developed rapidly into cylindrical carcinomata. Dec. 22, 1897, I re-examined the rectum with the patient in the knee chest position and found a larger number of even larger growths than were discovered at the first examination. The larger ones were sessile. As it was evident that it would not be possible completely to extirpate these growths, and in view of their probable development into carcinomata, I advised amputation of the rectum.

Operation, March 19, 1898. Colostomy by Maydl's method. After packing the colon with iodoform gauze, I opened it immediately in the long axis and inserted Kelley's proctoscope, 22 mm. in diameter, 9 cm. downward and 8 cm. upward from the colostomy wound. I therefore was able to examine the rectum into the sigmoid flexure and into the transverse colon. Had I found that the adenomata extended upward into the colon to any great distance, I should have closed the bowel

and abandoned further operation. As nothing abnormal was seen in either direction I decided later to amputate the rectum. The wound in the colon was therefore closed with Glover sutures temporarily and was permanently opened at the end of a week.

Rectal operation, April 6, 1898. The ordinary Kraske operation was done, the sacrum being divided at the level of the third foramen. The prostate urethra and bulb of the corpus spongiosum and a portion of the wall of the bladder were exposed. Thirteen cm. of the rectum were removed (Fig. 5). A small rent was made in the peritoneum, but was immediately sewed up. Immediately above the growth the rectum narrowed very sharply to a calibre scarcely larger than the forefinger. Owing to the height and small size of the rectum, there was great difficulty in invaginating the lower end. At the end of the sacrum it was not possible to draw the soft parts together, and in consequence a considerable dead space was left, which I packed with iodoform gauze. A certain amount of reactionary hemorrhage took place that night, which required several sutures to be cut and a repacking with gauze. The day after the operation his temperature was 101.8 but on

Figure 5.—Specimens removed in Case 2. Rectum and coccyx and part of sacrum, removed in two pieces.

the second day had fallen to 99 degrees. From then until the tenth day it fluctuated between normal and 100 degrees, but after that was entirely normal. The dead space left had slowly filled up, but was not quite cicatrized when he left the hospital, early in June. Since then it has entirely closed and he is in excellent health.

THE MEDICAL ASPECTS OF APPENDICITIS.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June, 7-10, 1898.

BY H. A. HARE, M.D.

PHILADELPHIA, PA.

In reading this paper on the medical aspects of appendicitis I am well aware that in view of the beliefs of some surgeons I am ordered to lead a hopeless cause. I hope to show, however, that this is not the case, although it is necessary for us to arrive at a definite idea as to what this title means. If it refers to the medical treatment in distinction to the surgical treatment and in the sense of the use of medicines in place of operative interference, then I am the wrong one to have asked to write on it, not that I believe that all cases are operative, but because I believe some are and some are not. If the diagnosis of the appendicitis is at issue other lines of experience must

be followed out, and if the pathologic aspect of the case is before us, still other thoughts must be expressed. Taking up for consideration the diagnosis of appendicitis, I may first point out that he who asserts that diagnosis is always easy has not seen many cases and probably mistakes other maladies for this one, and that it is the experience of active practitioners that cases continually occur in which the very gravest doubt as to the character of the case must arise. The extraordinary variation in the severity and locality of the pain as it occurs without palpation and with it, the difference in its character in various patients, and finally the extraordinary dislocations of the viscus anteriorly, posteriorly, above and below and behind the liver, make us think of the disease whenever a disturbance occurs in the abdomen, for cases have been recorded in which the appendix has been found almost anywhere and there is in the current number of the JOURNAL (June 4) an instance recorded in which the appendix was found under the left clavicle. Nor are we to expect to find the morbid lesions alike in any two cases. In some there is pus in excess, in others a small gangrenous tip with no pus or but little, in a third class a large indurated mass surrounding the appendix as a nut-shell surrounds its kernel, and it is an unfortunate fact that the more fulminating the inflammation, the more dangerous the condition and the fewer the physical signs. Indeed, aside from pain and general systemic symptoms, no signs are to be found. In the gangrenous type pain is often but a fleeting symptom and the speedy development of septic painless peritonitis misleads the physician, who can not elicit it even on pressure. Nor are we to regard appendicitis as being always an acute process. It is often subacute or chronic, insidious and provocative of aberrant symptoms which mask the real trouble. Lately I have seen a lad of nine years who was seized while at the sea-shore with indefinite pain in the belly occurring in paroxysms. He had fever, and the local physician gave him quinin and frankly said he knew not the cause of the fever. His fever disappeared and he returned home only to go to bed in a few days with fever persistently remaining about 104 degrees and no other symptoms. Finally repeated examination revealed right iliac pain, referred to the epigastrium on deep pressure, and the diagnosis of appendicitis of a subacute variety was made. Some days later he developed well-marked typhoid fever, the local appendicular signs disappearing under the local use of cold. I believe that this patient had a typhoid infection of the appendix. Another case seen by me and afterward by Dr. Keen is instructive.

A man 43 years of age suffered from what was apparently a violent attack of appendicitis, in the summer of 1896. At that time he suffered from one attack of severe pain which he believed to be due to cholera morbus, and a few days later suffered from another attack of much less severe pain, with, however, a general sensation of illness which forced him to go to his bed. An examination by his physician revealed the fact that he had a marked swelling in the right iliac region, which was not only to be felt but which could be readily seen. From that time until the first of March, 1898, he was entirely free from any symptoms in connection with his appendix, the swelling disappearing within a week after it was first noticed, upon the application of counter-irritation, cold, and absolute rest in bed. In March of this year he presented himself to me complaining of ach-

ing pains through the bones and through his entire body and a general feeling of illness. The symptoms were more characteristic of influenza than of any other ailment, but no fever was present. Two days later I was sent for to see him at his house. I found him dressed and in an arm chair, feeling quite wretched, and with general diffused pains as before. His temperature at this time was 102½. I had already examined the right iliac region when he was at my office, because of his history of appendicitis, and I now made another thorough examination with negative result. His temperature continued to rise higher from day to day and he gradually developed, as his fever progressed more and more, pain in the right side of the abdomen until finally it hurt him to extend his leg or to raise his arm above his head. There were, however, at no time any signs of induration or very great tenderness on pressure in the neighborhood of his appendix. At this time he developed the rash of typhoid fever, his liver and spleen were found to be slightly enlarged, he had the curious odor of typhoid fever and presented a typical picture of enteric fever. At the end of his second week of typhoid, the pain in the right iliac region having increased, daily examination gradually revealed slight swelling in the right flank, which finally extended from the border of the last rib to the anterior superior spine of the ilium, but the tenderness was very moderate. He was seen in consultation with me on two occasions by a well-known physician, the second occasion being due to the fact that I had insisted upon the family allowing me to call in a surgeon and, owing to their fear of the knife, they asked for a medical opinion as to the wisdom of calling in a surgeon. This physician entirely agreed with me as to the necessity of interference. Dr. Keen, being called, also agreed and made an incision in the neighborhood of McBurney's point, from which escaped a pint and a half of exceedingly fetid pus having the characteristic odor of typhoid stools, but containing no fecal matter. A bacteriologic examination of this pus showed no typhoid bacilli, but the bacillus coli communis, and, floating free in the pus was a large mass which we thought, at first glance, to be a sloughed-off appendix, but which Dr. Keen asserted, upon dissection, was sloughed-off omentum. After the operation the patient, who of course was desperately ill, gradually progressed to a complete convalescence. We have then a case of typhoid fever, complicated by a recurring appendicitis perhaps due to impaired nutrition of the patient, in which the symptoms of typhoid and appendicitis were so complicated, and so masked one another that a diagnosis was most difficult, and had the peritoneal cavity not been walled off by a wall of lymph, there is no doubt that my patient would have died of septic peritonitis, complicating typhoid fever.

There are other cases in which the typhoid symptoms are due to septic absorption from the appendicitis and the diagnosis is that of typhoid fever first and appendicitis afterward.

As to the diagnostic symptoms of acute cases, rigidity is certainly of great importance. Its presence always makes one call the surgeon at once for his opinion, and I do not call a surgeon who believes that every case should be operated on, rather one who will be broad enough to know that judgment and expediency are to be applied to the decision of every case. I call a surgeon not as I would call a servant to do as I tell him, not as a master to direct what I shall do,

but as a colleague who will present the surgical aspects to me as I will the medical ones to him. He is to take part in my joys and sorrows and not to be weak and indecisive nor dictatorial and ambitious.

I have recently published in the *Medical News* some interesting cases of appendicitis which show how one may be harassed by conflicting experiences. In one case I implored, besought, pleaded and insisted that a young fellow with a history of nine attacks in six months should have an operation. He had an immense mass of inflammatory material about his appendix. He finally consented. One of the most eminent surgeons living operated. Stercoraceous vomiting speedily ensued with collapse and death. I forced this man to an early death. In another instance I advised delay, because after this experience I had lost my nerve, for it came to my hands a few days after. Death met me again. Another case had a sharp attack of pain with every classical sign of the disease. A surgeon said operate. The weather was excessively hot, the patient a feeble woman of 50 and I felt sure the operation would kill her. I called a medical consultant who agreed with me. No operation was done and the patient is now well and has had no attack since. I could go on with such cases indefinitely and reach no clearer ideas as to the subject.

As a matter of fact we can divide all cases into three sets: those which undoubtedly should be operated on at once, those about which doubt exists and those that get well of moderate attacks and have no more. One man injures his knee-joint, it must be opened; another injures it and the question arises, shall we save it; a third gets well without the knife with good sensible external treatment. There are no cases to be met with in practice which need identical routine treatment, for individuals differ, infections differ and circumstances differ. When the profession recognizes that appendicitis is a disease in which medical and surgical opinions are always to be married and when dogmatic operators cease to combat dogmatic physicians then will these cases present the best statistics of recovery.

Finally a word as to opium. It will not cure the disease, nor will it limit it. If it is used to excess it is harmful in more ways than one; but used with judgment it is of value to take the edge off the excessive pain and to support the system. If it is used in such amounts as to remove the pain and produce sleep, it is abused. The question is not opium or no opium, it is whether it is needed as a palliative of pain until the diagnosis is clear or the surgeon is ready.

THE EARLY TREATMENT AND INDICATIONS FOR OPERATION IN APPENDICITIS.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY WILLIAM M. HARSHA, M.D.,

PROFESSOR OF OPERATIVE AND CLINICAL SURGERY, MEDICAL SCHOOL OF UNIVERSITY OF ILLINOIS, CHICAGO.

Although appendicitis is more than ever regarded as a surgical disease, a majority of cases are first treated by medical men. To one trying to follow the drift of opinion on its various phases as expressed by those best informed, it is clear that there is yet a great lack of agreement on many important points.

In view of the importance of the history of any given attack a precise diagnosis is indispensable at the earliest possible time. Physicians should therefore carefully examine every case, beginning with or attended by abdominal pain. The diagnosis established, the next step will be either medical treatment or surgical operation. The number of those who favor immediate operation, except in fulminant cases, is small, as compared with the advocates of an observation period of from twenty-four to thirty-six hours. It is the general belief, in which the writer shares, that a considerable number of cases seen in the beginning of the first attack are either aborted by medical treatment or subside spontaneously by the end of twenty-four hours, and of these a majority have no recurrence. The advocates of immediate operation have to figure on a degree of danger, from operation or sequelæ, which equals, if it does not exceed, the slightly increased danger of the smaller number that will require operation at the end of twenty-four or thirty hours. The advantage and the weight of opinion, if we may judge from the reports during the past year, are on the side of waiting this short period, except in fulminant cases. In this class there is a general agreement in favor of immediate operation.

In moderate cases the early medical treatment will be considered. Absolute rest in bed, abstinence from food, hot or cold applications locally are agreed upon as of the first importance. Hospital care, or that of a trained nurse, is almost as uniformly considered essential. In directing the local applications, antiseptics should be used with a view to possible operation. The pulse, temperature, degree of pain, general distress and appearance should be carefully noted. Failure to relieve pain or to render it endurable by these means will suggest anodynes in some form. With reference to the use of opium there is the greatest difference of opinion expressed by the best of physicians and surgeons. Prof. William E. Quine, from whom I heard a clinical lecture on appendicitis fifteen years ago, recently expressed in his most impressive and explicit terms the same endorsement of the use of this drug when indicated, which characterized the lecture to which I have referred. Herzog¹ says that those practitioners who use it have the satisfaction that their cases recover as often, if not oftener than those in which it is not used, and, if so, they probably remain more comfortable during the painful stages of the disease. Many surgeons deplore its use because, as it is said, "it puts out some of the danger signals." Judging from a majority of opinions and from my own experience in a considerable number of cases, it is my firm belief that there are distinct advantages in its use in certain cases and stages, if used with proper precautions. The influence on pulse and temperature of opiates in quantity just sufficient to promote the comfort of the patient should not confuse the observing physician, especially if the patient is under the observation of a competent nurse. The amount required will further indicate the severity of symptoms. Codeine hypodermically is probably the best form in which to administer anodyne, causing less gastric disturbance and interfering less with catharsis, should that be indicated at the same time. Should vomiting be present and further stomach evacuation desired, warm water to facilitate emesis, either as a drink or by stomach tube, is indicated before the opiate is

¹ Deutsche Zeit. Chirurgie, 1897, p. 214-230.

given. The coal-tar products, owing to their greater interference with pulse and temperature and their less efficiency as pain-killers, should not be used. It is scarcely believed by anyone now that opium shall be the mainstay or sheet-anchor in the management of appendicitis, as was formerly taught, but a majority justify or recommend its use in a cautious manner. It relieves the shock of pain, is humane and palliative, and sometimes curative by relieving inflammatory spasm, quieting and favoring limitation of the inflamed area and resting the nervous system.

The use of cathartics is the next mooted question in the medical treatment. McBurney² says: "Cathartics are not indicated at the beginning of an attack, as they tend to increase gastric, intestinal and general unrest." A majority of recently expressed opinions, however, favor prompt and free catharsis at the earliest possible time, provided the attack has not been attended by a profuse diarrhea. A majority of cases probably are preceded by constipation; many cases follow the ingestion of a generous meal; and many cases, approximately 25 per cent., are either cut short or spontaneously subside after thorough evacuation of the bowels. Stenosis of some part of the appendix plays an important part in the evolution of an attack, and free serous depletion is indicated to eliminate the congestive element of the stenosis; with the safety-valve free and fecal circulation re-established, the danger of explosion or perforation must be lessened, although infective inflammation may go on to the destruction of the appendix.

During the first twenty-four hours in moderate cases in the first attack there is no material impairment of the appendix wall; there is, therefore, slight danger of perforation; while the hope of aborting the attack or securing a better condition for operation lies in early and free intestinal clearance. With this, as in other phases, the indications must be observed at the bedside and every case considered by itself. Opiates or cathartics should not be advised nor interdicted because the patient has *appendicitis*, but because of special indications.

As to the best means to catharsis, we may consult the taste or idiosyncrasy of the patient. Enemata will relieve the colon, small doses of mild chloride of mercury alternated with some acceptable saline will answer best for the intestinal tract generally. Epsom salts causes serous depletion with little peristalsis. In some cases where there is persistent vomiting, and medicines cannot be given by the stomach, I would suggest the use of hypodermic medication with the same purpose in view, viz., catharsis. This suggestion of hypodermic purgative administration is not new, but so far as I know it has not been applied to appendicitis, although recommended in general abdominal surgery as indicated. In 1893 a paper was read by Rohe and Wade before the Pan-American Congress, detailing the results in one hundred injections of 2 per cent. solution of sulphate of magnesia in doses of 1.86 gr. to 4.5 gr. Injection was made in the arm. The results were positive in 67 per cent. of cases, average time for effects seven hours, forty-five of sixty-seven times produced watery evacuations. Inquiry as to other drugs by which the purgative action might be hastened developed the knowledge of the veterinary practice of hypodermic use of eserine, or what is known officinally as sulphate of physostigmine. This drug increases intestinal

peristalsis very promptly and markedly, and intestinal secretion somewhat less. The writer has tried hypodermic tablets, prepared by Sharp & Dohme (one-fiftieth gr.), and suggests as worthy of further trial a combination of sulphate of magnesia, as recommended by Rohe and Wade, with sulphate of physostigmine hypodermically as a means of prompt catharsis in stages where increased peristalsis may not be considered dangerous. Other indications for use of the combination are obvious and where oral administration is impossible or difficult.

In cases preceded by violent catarrhal diarrhea, no doubt the congestive stenosis is a most important factor, whatever may have excited the local inflammation. Treatment directed to this condition is then indicated; rest, abstinence from food, warm fomentations as detailed. If evacuation has not been complete, a saline or castor oil will aid in its accomplishment, or the hypodermic method mentioned, after which a hypodermic of codeine will aid in quieting the intestinal tract. If evacuation has been complete, rest alone or with codeine may answer. With the subsidence of the catarrh of intestines the local appendicular trouble may disappear. As much in the way of treatment has probably been named as will occupy the first day; in this early period great pains should be taken to locate accurately the seat of trouble, as the future may develop urgent need of accurate location and tympany may obscure it. Should there be recession of symptoms at the end of twenty-four hours with return of patient to comfort and normal condition, he will probably go on to recovery without abscess or other serious trouble. The means named, together with any safe minor symptomatic treatment that may be clearly indicated, extending over the first twenty-four hours, will aid in cutting short many attacks if the writer can judge from his own experience. Should these fail or the attack not subside in the time named, or show marked tendency thereto, an operation should be done in every case, as a complete and safe procedure can at this time be confidently undertaken. Failure to act at this time subjects the patient to dangers that no one can estimate. This does not mean that operation is to be undertaken at any time after twenty-four hours. Richardson's opinion that there is a time too late for safe early operation and too early for safe late operation, I believe to be sound, although that time cannot always be determined. Most fatal operated cases are either due to delay until this intermediate period or until general peritonitis has set in.

In fulminant cases, the earlier the operation is done the better, and no medical treatment except rest, fomentations and opiates to make life endurable until operation can be done are here advised. If the surgeon takes this view of the subject and is called within the first twenty-four hours, in all cases the mortality will be reduced to a minimum, and the operative treatment will become established beyond a question in fulminant or progressive cases.

The trouble with the prevailing practice is that the surgeon is not called in time. In the later stages of the disease is where the indications for operation are not so clear, and unfortunately this later time is when the surgeon is often called. The uncertainty as to intra-abdominal conditions in appendicitis is one of the best established facts in surgery. Dr. Murphy wisely enjoins those who may expect his services to call him early.

² Dennis, System of Surgery, Vol. IV, p. 415.

Those who favor awaiting abscess formation should bear in mind that such occurrence is uncertain, and that general peritonitis may set in; that should abscess form, it may be deep-seated and central, and present insurmountable obstacles to drainage; further, that in event of abscess favorably located, the appendix may not always be removed with safety, and finally that hernia is likely to result after drainage cases.

In the intermediate inflammatory stage, characterized by serious systemic disturbance, where the process is still limited but not circumscribed by safe adhesions, it is probably better to use opiates to quiet peristalsis and await the walling off process. Here the patient is in imminent peril with or without operation, but the testimony of a limited experience and considerable observation convinces the writer that the least danger attends delay. It is the large mortality attending operations in this stage (and in general peritonitis) that discredits surgical intervention. It is in this stage that decision as to operation is most difficult. The great systemic disturbance many times determines the operation when it should favor delay. No other phase of the disease except approaching or present collapse of the diffuse suppurative period is so dreaded by the surgeon, and it would be a wonderful relief to him, as well as a great boon to the patient, if he could forestall that condition by early operation. If an abscess has formed when the surgeon is called, and the more acute symptoms have subsided, operation is indicated except when such abscess is centrally and deeply placed. In such cases, owing to the great difficulty of draining, it may be better to take the chance of spontaneous evacuation through safe channels. By operation in the abscess period the weight of opinion is overwhelming in favor of leaving the appendix rather than to break up protective adhesions. Should the appendix be present or be found within the cavity, it should, of course, be removed. Should the patient suffer a recurrence from the non-removal, which occasionally happens, the rule of early operation applicable to that condition will yet work out his salvation. Who of us would not rather submit to the knife twice and recover, than have one *complete* operation and die?

In recurrent cases or those in which chronic inflammatory process is present, operation should be done. In the second attack too early operation can not be done. If the patient is seen after the second attack, interval operation is agreed upon as best, the safest time being two weeks or more after the attack. In chronic cases we are in constant danger of immediate or precipitate perforation, which adds greatly to the danger of operation, and still more danger to delay; it is therefore safer to remove the appendix and forestall imminent danger.

In considering the principles that should govern the operative treatment of appendicitis, we should not be influenced by the fact that their practice in the hands of inexperienced operators may result in a greater death rate than if left to nature. Van Hook³ expresses the belief that cases of acute perforative appendicitis will show a higher percentage of recoveries under medical treatment with incision of presenting abscess than when operated by surgeons who are gaining their first experience. The inference is obvious, but that should not weaken the position of

those who believe in early operation by competent surgeons. Morris' well says, "The teaching of a correct surgical principle should not be abrogated on the ground that many improperly prepared men will try to carry it into effect."

Grieg Smith says in reference to the mooted questions arising in consideration of this subject, "It is impossible to be definite and wrong to be dogmatic." The surgeon can only decide in any given case at the bedside. There is a considerable number of writers on the subject who advise operation as the safer plan in case of doubt. Although American surgeons are charged with too great readiness to operate, I believe the encouragement in this direction has come from those with the largest experience and are therefore best able to estimate the advantages of early operation. I believe the mortality can be reduced to less than 5 per cent. if competent surgeons apply these principles.

Columbus Memorial Building.

PENETRATING WOUNDS OF THE POPLITEAL ARTERY.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association held at Denver, Colo., June 7-10, 1898.

BY GEORGE W. MIEL,

DENVER.

Though of small experience in dealing with penetrating wounds of the popliteal artery, the especial gravity of this accident itself, or because complicated with other injury, and vice versa, has impressed me with the desire to look well into the subject, and giving my deduction, ask the criticism of this society.

By carefully investigating a deep external wound in the vicinity of the popliteal artery, extended if need be by dissection, we exchange uncertainty for certainty. Should such a wound communicate with the artery, we should remember a small puncture, even if occluded, may ulcerate and occasion secondary hemorrhage, which should at least put us on our guard. An incised wound of more than an eighth of an inch requires ligation with complete division of the vessel between. A penetrating laceration of even less extent calls for the same procedure. A considerable laceration, and an uncomplicated gunshot division of the popliteal artery, requires double ligation away from the wound in a sound portion of the artery, with extirpation of the intervening wounded portion, and ligation of considerable branches given off. A true puncture wound from without and communicating with the popliteal artery seldom occurs. The artery is occasionally divided from within by pointed or edged exostosis. *Procedure.*—Intermittent digital or shot-bag compression at the pubis, unless distension by thrombus or diffuse traumatic aneurism is so great as to threaten the collateral circulation, when, with provision against hemorrhage, dissection must be made to turn out clot and tie ends of artery.

In dealing with complicated wounds of the popliteal artery we take up one of the most difficult problems the surgeon is required to solve: When to amputate, when not to amputate, with his patient's life, deformity and impaired usefulness, weighing in the balance against extra hazard—but life, limb and perhaps unimpaired usefulness. While justified in

³ Jour. Am. Med. Association, Feb. 20, 1897.

⁴ Jour. Amer. Med. Association, May 8, 1898.

taking chances to save limbs, we must well consider the possibility of greater loss through complication, and of life itself. Our first consideration should be for life.

A wounded vessel of great importance, a fractured bone, even badly comminuted as from gunshot injury, a perforated joint, a considerable separation or loss of integument, in themselves do not necessitate amputation. In combination, however, they may call for it as the wisest procedure, or may necessitate it for the preservation of life, or as offering the better chance for life. Gangrene supervening upon injury dividing the popliteal artery is in the large proportion of instances fatal. The popliteal artery must perform its function or the collateral circulation must take up its work partially or wholly, besides its own, or the parts below perish.

As complicated division of the popliteal artery, because of its protected position, is usually the result of extreme violence, which these structures quickly resent, the resulting inflammation has a most serious effect upon the collateral arterial supply to the leg. The tissues already held nicely taut by the tough, resisting and closely attached enveloping deep fascia, leave only the popliteal space relaxed. Tightened then by effusion without, and within the joint, inflammatory deposits, and perhaps thrombus, the collateral vessels, instead of accommodating themselves to the increased amount of work, are actually, I should think, in most instances unable to perform their accustomed work. In our effort then to save a leg, it seems plain that our own wound in dealing with rupture of this artery, or the communicating wound of violence, should be never more than loosely closed; but preferably dealt with by nice grouping of the deep structures and neat tamponade; in some cases using, if thought best, provisional, or loose deep suture below the fascia latta and integumentary structures overlying. The life of the leg depends upon relaxation of the enveloping covering, and avoidance as far as possible of harmful constricting pressure.

Too often, unfortunately, when the popliteal artery or vein is ruptured, in our unsuccessful effort to save a leg, a life is lost. Gangrene supervening is moist, and of the quickly spreading or fulminating type; and in vitiated subjects it may spread from the wound. Demarkation is absent; and decomposing fluids pass readily into the general circulation. Amputation then, a last resort, occurs at the worst possible time and must be done far above. It is then at the time primary amputation can be practiced, that modern reliable, and properly classified statistics would be of invaluable service in this desperate emergency.

In our present text books, so far as I have seen in a considerable search, statistics upon injuries invading the knee are grouped in a general way with injuries involving the great articulations, which is unfortunate and misleading. The serious injuries involving the knee, and which raise the question of amputation, necessitate separate, definite, and full statistics. The nearest approach to such compilation is available to us in the separate instances, and small collection of cases, of division or rupture of the popliteal artery, reported from year to year in the *Annual of the Universal Medical Sciences*: in aggregate few, and by far the larger proportion are instances of ligation and various procedure for completely ruptured popliteal aneurysm.

Our available statistics attending double ligation of

the popliteal artery in uncomplicated cases would indicate at present a mortality of some ten per cent. While each case of complicated perforation of the popliteal artery must be judged separately, something approaching definite action may be applied in accordance with carefully compiled statistics based upon the antiseptic system. Primary major amputation, while always a grave emergency operation, other conditions being equal, differs in degree. Amputation, of necessity, is accompanied with more shock than that which attends what might be termed amputation of seeming necessity, or expediency. Considerable loss of blood naturally adds seriously to the issue of ligation or amputation, notwithstanding auto, mediate arterial, or saline transfusion.

If then we can have available statistics of complicated penetrating injury—division or rupture—of the popliteal artery in their several combinations, with result of effort at saving the leg—"waiting"—in contrast to statistics of amputation, we can proceed more definitely in our patient's better interest. And if it shall be shown that primary amputation offers unquestionably the better chance for life, the patient concurring, and other circumstances being equal, that should be our procedure. In the words of Connor, "Final judgment as to the necessity of amputation in any given case must be sustained by the latest surgical experience."

Today the telephone and better hospital facilities and appointments permit us to take greater chance than formerly. Taking the chance, the patient must be under frequent scrutiny that at the first sign of approaching gangrene—cold leg and marked stasis, or erysipelas—we can, and should, resort to proper amputation above the knee.

DISCUSSION.

Dr. B. MERRILL RICKETTS of Cincinnati—This subject should receive more attention in the future. I desire to refer to Dr. Crile's paper in connection with this subject, as he has demonstrated that the common carotid artery may be obstructed by pressure from twelve to twenty-four hours without injurious effects, and has shown that there is no danger in such obstructions. The carotid has been clamped in a human being during an operation for a removal of a tumor of the neck. Within the last ten days I have torn off the external iliac vein in removing a tumor from the iliac fossa, and no serious consequences have resulted after ligation. I believe it impossible to suture or make anastomoses by any of the methods so far devised, but in future it looks as if we should be able to do something for penetrating the wounds of these vessels. My brother had a case fourteen years ago where the deep profunda was shot off close to the femur, and extensive hemorrhage followed. The leg was cold, and an amputation was performed at the hip joint, but the patient died forty-eight hours later. Today we would doubtless adopt other measures and be more energetic in trying to save the limb. It might be better to divide the artery rather than sew it up.

Dr. OLIVER of Cincinnati—I recently had a case bearing upon this subject in a boy 12 years of age, whose foot had been caught in the wheel of a carriage, producing a compound fracture of the femur at the epiphyseal line. The lower end of the upper fragment projected through the popliteal space, and there was a large ragged wound corresponding to the point of exit of the femur. When I saw the case three hours later, pulsation of the popliteal artery could be plainly felt in the wound. The fracture was reduced by extension and pressure, and the foot appeared normal the next morning, but on the second morning symptoms of obstructed circulation were present, and on the ninth day amputation had to be performed. In a dissection of the leg, after amputation, considerable effusion was present in the deep fascia, which was probably the cause of the obstruction to the collateral circulation and the resulting gangrene. Two inches of the popliteal artery were found to have been destroyed, and I was very much impressed with the fact that the unyielding dense fascia had been responsible for the gangrene of the limb. In future cases I shall open the deep fascia thoroughly, as I do not see any reason

why we should not save these legs and convert the operation into a simple ligation of the popliteal artery.

Dr. TINKER of Philadelphia—Experimentally the descending aorta has been divided in an ass and the animal recovered perfectly. When it was killed several months later, firm union was found to have taken place between the divided ends.

Dr. B. MERRILL RICKETTS—As to the size of the artery, anastomosis seems to be more successful in the larger arteries, and the experimental work referred to by Dr. Tinker would seem to prove this, the artery in the ass being very large.

Dr. MIEL, in closing—As to the temporary closure of the vessels, this is especially desirable in dealing with wounds about the mouth, and if this can be successfully accomplished we shall have a much better method than in permanently ligating the common carotid for conditions about the throat and tonsils.

Dr. Oliver's case is one of the kind which prompted me to read this paper. I had a case of a man in whom amputation of the foot had been performed, and although I believed good circulation was present, gangrene supervened and the leg had to be amputated, the man subsequently dying from septic infection.

I remember another case of compound fracture of the knee where amputation had been deferred. I knew nothing of the involvement of the popliteal artery in the case, but subsequently ascertained that a spurting of blood had been noticed at the time of the injury. The brother of this patient objected to operation, and unfortunately very often in these cases these objections cannot be removed until it is too late to operate. I believe that compression of the vessels had much to do with causing the gangrene.

As to end-to-end anastomoses, if they can be successfully accomplished, we are rid of a very formidable operation which has carried away many individuals.

ANEURYSM OF THE AORTIC ARCH.

LIGATION OF RIGHT SUBCLAVIAN AND COMMON CAROTID ARTERIES.

Presented to the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY B. MERRILL RICKETTS, Ph.B., M.D.
CINCINNATI, OHIO.

While any point throughout the arterial system may become aneurysmal, it is aneurysm of the aortic arch to which special attention will be given in this paper. The pathology, which is fairly well understood, will not occupy much space, but give place for more thought upon the treatment, which has, from the time of the great masters—Antyllus (fourth century), Anel (1710) and John Hunter, baffled the skill of all. Its successful treatment at the present time is practically *nil* in ways other than surgical. Even this method has been of but little consequence until within the last few years, when by accident Christopher Heath (1865) discovered the beneficial results to be obtained from ligation of the right subclavian and common carotid arteries, supposedly for aneurysm of the innominate. Death four years later revealed aneurysm of the arch and much new tissue within the sac. Nine additional operations have been made since then by as many different operators, with most brilliant results in the seven which survived the operation, and had not the mortality before the days of asepsis been so great, many more cases would no doubt have been subjected to such surgical measures. Even at this late date, the ligation of these arteries, for this condition, does not receive its merited attention.

Thus it is, perhaps, that the obstruction of these vessels for many conditions have been made fewer, but now that more perfect methods have been inaugurated—methods which enable the work to be done with slight, if any, mortality—much more will be

accomplished in this direction. There is no form of aneurysm, except those intracranial, which has heretofore offered so little encouragement in the way of treatment.

The methods of Tueffnell and Schott have been followed by favorable results in a few cases. In point of fact, recumbency and diet are to be advised in all cases of aneurysm, as are occasionally baths and graduated exercises. These, in conjunction with mercury and the iodids, should, as a rule, be resorted to in all forms of aneurysm, especially of the arch and innominate, before surgical intervention. They should also be applied after the ligation of aneurysmal vessels; especially are they beneficial in those of syphilitic origin.

The interesting demonstrations of Draste (1895) upon the dog, by injecting a solution of gelatin into the veins, have warranted its introduction into the first portion of the arch in man, where aneurysm of the arch existed, with, however, negative results. Macewen's method of introducing, first needles, and then wire, into the sac, both with and without galvanism, has proven itself of great value, the most marked beneficial results having been obtained by Hare some fourteen weeks ago. He introduced ten feet of gold wire into an aortic aneurysm through a hollow needle, to which galvanism was applied, gradually increasing from three to seventy milliamperes. Indeed, this seems to be a most rational method of dealing with a limited number of these cases, and while the object of any method is to produce coagulum, it would seem that fragments of it produced in this way (especially if the opening into the main vessel should be large) would be more likely to become detached and enter the general circulatory system.

At present, there is absolutely no means of determining the character of the opening into the sac. The method would seem to be applicable in those cases with one or more small openings. Even then the wire might pass from the sac into the artery; thus it is that this method is attended with great risk and mortality. It would seem to be the extremely large opening that would preclude the possibility of beneficial results from any method.

While the autopsy in Dr. Hill's case three months after ligation (*Cincinnati Lancet and Clinic*, March 19, 1898) showed it to be one of the most unfavorable for either ligation or the introduction of wire, large quantities of fibrous tissue had been deposited within the sac since operation. He was greatly benefited, so much so that he was enabled to return to his duties—those of a policeman—after a few weeks. He died suddenly from rupture of the right auricle, while sitting at the table eating breakfast. About twelve pounds had been added to his weight, and he was comparatively comfortable.

It may be argued that the ligation of the subclavian and common carotid arteries in this case superinduced the heart rupture. Had the left auricle subsequently ruptured, one might indulge in such belief. Of the 412 recorded ruptures of the heart (Hill) from all causes, but one of the right auricle occurred. It must therefore be presumed to be an exceedingly rare condition, and one not due to obstructing these important vessels. Diagnosis of aneurysm of the arch is not certain, as it may exist without detection of murmur or other symptoms. If discovered, its character must be absolutely unknown, except by autopsy. This, therefore, must necessarily make more uncertain

the proper course to adopt, and much speculation must ensue. The following classification might not be amiss: 1, those in which the right subclavian and common carotid arteries should be ligated; 2, those into which wire should be introduced; 3, those in which nothing should be done.

It may be that those in the first and second would be equally benefited by either procedure. That each has been beneficial to a very high degree there can be no question; in fact, greater benefit has been obtained by these two methods than any other.

The *modus operandi* of the second is more easily understood than that of the first, even though the first has been followed by more permanent and universal results. But the great underlying principle upon which rests the method of ligating the subclavian and common carotid arteries does not seem to have been discovered until the time of Wardrop. He it was who demonstrated that less resistance was necessary to produce consolidation of the contents of the sac than was formerly thought to be. It is, therefore, to be supposed that the obstruction of the innominate, or its branches, would be sufficient to more or less retard the rate of blood-flow through the sac. This retardation would necessarily seem to correspond with the opening into the sac, hence the amount of lymph deposit would be influenced. Now, it is not necessary to close a vessel that complete consolidation of an aneurysmal tumor may ensue. So it is that lymph may be deposited within the sac, first in the depression of its wall, and especially at the opening of the innominate.

The case herein reported was first referred by Dr. H. A. Beeson of Leesburg, Ohio, in the spring of 1897. Male; white; age, 40; family history negative. He complained of pain in right infra-clavicular region, extending beyond sternum, and in right arm, especially exaggerated on movement of arm, incapacitating him for his work—that of a blacksmith and wagonmaker. On examination, a swelling was found extending from middle third of right clavicle, slightly beyond median line, and extending over two or three intercostal spaces. No bruit could be found at this time. On questioning him, found that twenty-two years previous he had a suspicious sore upon the genitals. The diagnosis of aortic aneurysm due to syphilis was made, and the patient put on anti-syphilitic treatment. The few reports from him after were that he was improving, being at the end of three months able to resume his work. On the 15th of February last, Dr. Beeson again brought the patient to me. The pain complained of at his previous visit was even now not so severe; but he was becoming more and more short of breath, and was gradually losing flesh. Examination again showed swelling, slightly greater than before, and now a very decided bruit was found in medial line near junction of second and third portions of sternum. The bruit was especially distinct on the introduction of stethoscope into patient's mouth. The pulse was about eighty—full and strong. It is to be regretted that the sphygmograph was not used. An operation was advised and made. The patient was chloroformed, and under as nearly aseptic conditions as possible, the subclavian and common carotid arteries of the right side were ligated with kangaroo tendons; the former requiring seven, and the latter five minutes. The wounds were dressed with collodion. The patient made an uneventful recovery, and returned home at the end of twenty-one

days. After the third day, the bruit was less marked, growing gradually less as time progressed, until now no bruit is to be heard, but there appears to be great commotion within the dust walls on auscultation. The operation caused no appreciable change in the circulation, and the temperature was only slightly elevated for a few days, on the second day reaching 100. The chest prominence at time of patient's dismissal from hospital was much less than before operation, and pulsation that was distinct three weeks before almost gone, showing the rapid progress of probable consolidation. He has gained about twelve pounds, and now reports that he feels better than at any time for eighteen months.

The following conclusions are submitted:

1. The remedy lies within the domain of surgery.
2. There are but two such methods at the present time to be considered: (a) Obstruction of the right subclavian and common carotid arteries; (b) Introduction of wire or needles into the sac, with or without galvanism.
3. Either one or both of the operations should be applied in all cases after a thorough saturation with the iodids.
4. Ligation is attended by less danger, less mortality, greater and more permanent and universal benefit.
5. Ligation of the subclavian and common carotid arteries is less dangerous than ligation of the innominate. In point of fact, the latter should not be done.
6. The iodids should always precede and follow any surgical interference.
7. Extreme atheroma might contraindicate ligation.
8. Extreme atheroma might possibly indicate the introduction of needles, or wire, with or without galvanism.
9. Atheroma to some degree is present in the majority of arch aneurysms.
10. It is impossible to technically classify arch aneurysms.
11. The results of ligation in the case herein contained have been far more beneficial than was ever anticipated.

REMOVAL OF THE EPITHELIOMATOUS TONSIL, BY THE EXTERNAL ROUTE (PHARYNGOTOMY), WITH A REPORT OF TWO SUCCESSFUL CASES.

Presented to the Section on Surgery and Anatomy at the Forty-ninth
Annual Meeting of the American Medical Association, held at
Denver, Colo., June 7-10, 1898.

BY A. F. JONAS, M.D.,
OMAHA.

It is not our purpose today to discuss epithelioma from an etiologic or pathologic standpoint: these subjects belong to those who are more competent, and should receive consideration only from those whose authority is based on experimental research. As practical surgeons we are chiefly concerned in the clinical and operative aspects of this insidious, relentless and fatal disease.

We will direct our attention to the tonsil when affected by epithelioma. This, on first thought, does not seem to be the place for discussing diseases of the tonsil, but nearly every special field that is more or less surgical, will have in it more or less work for the

general surgeon. The field of laryngology and rhinology, in common with others, contains many diseases whose surgical magnitude and responsibility seem to require a general surgeon for their management. The cases which will serve to illustrate our theme today were referred by the specialist to the surgeon, therefore the cases were transferred from the department of laryngology to that of general surgery, and hence their presentation at this time and place.

The results from operative and other treatment of malignant disease of the tonsil have been so unsatisfactory, perhaps more unsatisfactory than when located in any other accessible cavity, that Butlin, after very careful research, exclaims: "The prospect of permanent relief by operation in any case of malignant disease of the tonsil is very small, even if there can be said to be any. Removal of the disease through an external incision (pharyngotomy) has hitherto proved a dangerous proceeding, and has not yielded as good results as operations through the open mouth." In future cases, pharyngotomy cannot be recommended and, unless the results produced by it are far better for the next series of cases than those which it has yielded hitherto, it must be condemned as an unjustifiable proceeding." This is certainly emphatic language by an eminent authority. And yet we cannot stand idly by without an attempt to remedy the existing condition.

With improved technique, increased experience and a more thorough knowledge of the dissemination of epithelioma and the more encouraging results from extirpation of epithelioma in other glandular organs, more especially epithelioma of the breast, as operated according to the painstaking and minute attention to detail as taught us by Halstead, we have been prompted to renewed efforts when the disease has attacked the tonsil. Fortunately, primary epithelioma of the tonsil is a rare disease, so infrequent indeed that those of large experience have seen very few cases.

I desire to place on record two cases of epithelioma removed by the external route, by the operation known as pharyngotomy.

Case 1.—M. H., mechanic, aged 40, American, married, has always enjoyed good health, except for recurrent attacks of tonsillitis extending over a period of five or six years, the attacks recurring at least once a year, and often ending in suppuration. During the intervals his throat was sensitive, much accumulation of mucus and frequent hacking cough. His family history was negative, none of his immediate relatives having been affected with carcinoma or tuberculosis.

During the last year, and since his last attack of tonsillitis, he has had increased tenderness and sensitiveness in the right tonsillar region, with occasional expectoration of blood, which he believed to have come from the right tonsil. Deglutition became difficult and painful. He had lost in weight, which he believed to be due to his inability to swallow proper food, his diet during the last three months having consisted largely of fluids. On inspection, the right tonsil was found to be enlarged, ulcerated on its median side. It was found to be very sensitive to the touch, bleeding easily. On palpation with the finger it was found to be hard and irregular over its entire surface. It was slightly movable. The pillars of the fauces were not involved, and the entire process, from the mouth seemed to be confined to the tonsil itself. The pharynx and naso-pharynx were reddened and slightly edematous. The opposite tonsil was moderately enlarged, but to the touch with the finger, as well as in appearance, presented nothing that would suggest malignancy. Beneath and slightly posterior to the angle of the right lower jaw was found an enlargement, the size of a hickory nut, which was painful and tender on pressure. The diagnosis of epithelioma of the tonsil was made. It now became a question whether this mass should be removed through the mouth by excision, galvano-caustic snare, or by the external route through the submaxillary triangle. On

further examination it was found that the entire growth could not with certainty be removed through the mouth. A pharyngotomy was then decided upon.

Under chloroform anesthesia, a triangular flap was reflected forward, the lines of incision extending along the lower margin of the lower jaw, beginning about midway on the horizontal ramus and extending to the mastoid process, and thence downward along the anterior margin of the sterno cleido mastoid muscle, to a point opposite the cricoid cartilage; the submaxillary and superior carotid triangles were exposed. The enlarged and affected gland was situated within the submaxillary triangle; by means of blunt dissection the surrounding structures were separated without much hemorrhage. The sterno cleido mastoid, together with the carotid artery, the internal jugular vein and pneumogastric nerve were retracted posteriorly with blunt hooks. The diaphragm, mylohyoid, hyo-glossus were likewise retracted. The tongue now became unmanageable, interfering with respiration, so it was drawn forward and held by means of a vulsellum forceps. The left index finger was now introduced into the mouth and pressure made outward against the tonsil. The head was drawn strongly to the left side, and by means of a blunt dissector the tonsil was gradually separated, and the growth removed. The pharynx and larynx could now be inspected. With curved scissors and pincette the ragged margins of the wound were trimmed. No blood seemed to have entered the larynx. The pillars of the fauces were drawn together with catgut and the external wound closed with deep interrupted silk sutures. No drain. The healing process was uneventful. The patient was nourished with a feeding tube nearly two weeks, after which time deglutition gradually improved. The patient was last seen nearly four years after the operation, with no trace of recurrence.

Case 2.—H. M., farmer, aged 56, married, muscular, well nourished. He was always well until eighteen years ago, when he suffered from pneumonia, from which he completely recovered. He has been of constipated habit for nearly twenty-five years; has had hemorrhoids in mild form. His digestion has been imperfect, eructations of gas and occasionally of fluids, which he described as being at times sour, at other times bitter and again salty in taste. For many years he has had chronic pharyngitis, always greatly aggravated on exposure to cold, producing hoarseness and much tenderness during deglutition. About one year ago he began to experience pain, sometimes of a lancing character, and tenderness in the left side of the throat when swallowing. He coughed much, expectorating a muco sanguinolent substance, and occasionally clear blood in considerable quantity, which temporarily gave relief from pain. His medical attendant, believing that he had to deal with an hypertrophied tonsil, attempted its removal, and did remove the larger part with a tonsillotomy. Within a short time the pain increased, the muco-purulent expectoration appearing in augmenting quantities, until in a few weeks he was unable to sleep without opiates. He consulted Dr. Kinsler, who diagnosed epithelioma of the tonsil and referred the case to the writer for operation.

On inspection a hard, nodular, ulcerating, easily bleeding mass, occupying the site of the left tonsil, projecting toward the uvula and extending upward along the anterior and posterior pillars of the fauces to the soft palate, and downward to the margin of the epiglottis. This mass was lightly movable, very tender, and bled easily. On external palpation was found, immediately beneath the horizontal ramus of the jaw at its angle and extending forward nearly one third of its length, a hard ovoid mass the size of an English walnut, immediately adherent to the soft sublingual gland. Below this mass could be felt three hazelnut sized nodules.

The diagnosis of epithelioma of the left tonsil with involvement of the submaxillary lymphatics and the sublingual gland was confirmed.

Excision of the affected structures by an external route was determined and was done April 26, 1898. A strong silk suture was passed through the point of the tongue for the purpose of controlling this organ. A tracheotomy tube was at hand in case of necessity.

An incision was made, beginning at the mastoid process and extending downward to a point opposite the lower margin of the thyroid cartilage, and a second, beginning at the point of commencement of the first and extending forward along the lower margin of the horizontal ramus of the inferior maxillary to its middle point. This flap was, by rapid dissection, turned downward and forward, giving ample room for all manipulations. The external jugular vein was ligated between two ligatures and divided. On palpation a number of distinctly inflamed glands were felt beneath the sterno-cleido-mastoid. This muscle was divided diagonally and its ends reflected, giving

easy access to the involved structures. By blunt dissection it was found that the glandular enlargements were intimately and firmly attached to the internal jugular and both internal and external carotides. The pneumogastric nerve was isolated and the vein and arteries ligated, greatly facilitating the extirpation of all the nodes, together with the sublingual gland, which was plainly involved. After an exact hemostasis the head was drawn toward the right, the tonsillar mass was seized from the wound with a four-pronged vulsellum forceps and pressure from the throat outward with the index finger of an assistant; the pharynx was opened with curved scissors and the mass rapidly clipped away. It was now possible to inspect the pharynx, and several remaining masses were easily clipped away. The hemorrhage was slight and easily controlled. No blood had entered the larynx. After copious flushing and swabbing an attempt was made to approximate the buccal and pharyngeal mucous membranes with strong catgut, but with only partial success. The deeper soft structures were coaptated with same suture material and the integument with a subcuticular silkworm gut. A gauze drain was placed in the lower angle of the wound. The external wound, except where the drain was placed, united *per primum*. Feeding through a stomach tube began the day following the operation. The gauze drain was removed on the third day. It soon became evident that a communication with the pharynx had formed by way of the drainage canal, air and fluids escaping through it, making deglutition impossible, necessitating an unusually long period of artificial feeding through the feeding-tube, about six weeks. The fistula gradually closed. The pharyngeal wound granulated slowly but completely.

During the first ten days after the operation, a great difficulty was experienced in preventing the insufflation of mucus and the secretions from the pharyngeal wound; several severe attacks of laryngeal spasm were exceedingly alarming. On the third day the patient suddenly discovered that his vision in the left eye was abolished. On examination by Dr. Harold Gifford, he found a choked optic disc, which he believed to be due to an embolus. The central retinal artery was blocked by an embolus or thrombus, more probably the latter, as the extreme edema of the disc made it probable that the postciliary arteries also were blocked. It was also interesting to note that the tongue became atrophied on its left side, interfering somewhat with articulation. He continued to improve for nearly three months after his operation, when he was attacked with catarrhal pneumonia and died. No evidences of recurrence in the throat. He never, however, regained the power to swallow solid food; only thin liquids could be taken without the feeding tube.

In reviewing the technic present in our cases, it would seem that ample access to the diseased structures was obtained. The procedure is at best a severe and mutilating one. In the main the method followed in our cases was that of Cheever of Boston, who first removed a malignant tonsil by pharyngotomy. It seems that so extensive an operation as proposed and carried out by Czerny is hardly necessary. After a tracheotomy he made an incision, beginning at the angle of the mouth, extending downward to the anterior margin of the masseter muscle and thence to the level of the hyoid bone. The jaw was exposed and divided between the second and third molar teeth; the fragments were separated and the tumor removed, after requiring a section of the glosso-pharyngeal, hypoglossus, styloglossus and stylohyoid muscles and gustatory nerve. The bone fragments were reunited with silver wire. Nor does the method of Mikulicz seem necessary. He reflected a triangular flap as in our cases, the incision being very long. The jaw, after being exposed above its angle, was divided, and the ascending ramus resected, in order that better access to the gland might be had. We found that, after a thorough and extensive enucleation of all the cervical glands, whether visibly infected or not, after a division of the sterno-cleido-mastoid and its divided ends were reflected and hemorrhage carefully controlled, with a wide separation of the wound margins by retractors, and the head being strongly drawn to the opposite side, and strong traction downward of

the arm and shoulder on the affected side being made, sufficient room was obtained for all necessary manipulations. In both of our cases the entire larynx and naso-pharynx could be inspected, so that a thorough removal of all affected tissues could be made under direct ocular inspection.

In neither of our cases was a preliminary tracheotomy necessary, chiefly because all hemorrhage was controlled and the dissection made to the mucous membrane before the pharynx was opened.

The loss of vision in the left eye of our second case was undoubtedly due to an embolus, but to state just how an embolus could reach the eye is not easy to solve. It is the first observation of this kind made by us, after many ligations of the common, internal and external carotids and jugular veins, in the removal of nearly every variety of neoplasms in the region of the neck.

THE WAX-PARAFFIN DRESSING.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY SAMUEL H. FRIEND, M.D.

MILWAUKEE.

The wax paraffin dressing, as announced in the *Medical News* of October 23, 1897, is a mixture of equal parts of unpurified yellow beeswax and hard paraffin.

Composition: Equal parts, by weight, of unpurified yellow beeswax and hard paraffin.

Preparation: Melt these substances together, preferably over a sand bath (though a water bath will also answer), and after melting keep them liquified for one-half hour to complete mixture. The specific gravity of yellow wax is between .955 and .967; the melting point 63 degrees to 64 degrees C. (145.4 degrees to 147.2 degrees F.) Hard paraffin has a specific gravity of .900, and a melting point at 43 to 65 degrees C. (109 to 151 degrees F.) The object of boiling the two substances together for one-half hour is to diffuse them as much as possible. By covering the mouth of the bottle with wire gauze or absorbent cotton the mixture will attain a higher temperature and produce a more equal diffusion. Ehrlenmeyer's flask is useful to hold the dressing, as the glass of this flask is thin and offers a large base to melt the mixture quickly, although any bottle may be used. Forty to fifty grams of the dressing will melt within four to six minutes. As already detailed, the specific gravities and the melting points of the wax and paraffin are not the same, and as the substances are never equally diffused, the paraffin melts first, so that the mixture should not be used until the entire mass is melted. Another point worthy of note is that immediately after the mixture is melted its temperature at the bottom of the bottle is 105 C., while the top is 122 C. This difference of the temperature lasts but two minutes, at the end of which time the bottom layer registers two to three degrees higher than the top. The dressing is either directly spread upon wounded surfaces or upon dressings of absorbent cotton or gauze.

Properties: This mixture is sterile. It is light in weight, cohesive, rigid, ductile, tenacious, adhesive, air, water and germ proof, and has an agreeable odor, and solidifies instantly. As it is a perfect non-conductor it retains an even temperature about the

wound and hastens regeneration. Never irritating the skin, it can be easily removed. Upon the slightest pressure from below it allows free drainage. It will hold in suspension almost all of the well-known antiseptic powders. It will cover and retain in contact with the skin and other surfaces all medication. It will adjust itself to any part of the body and form a rigid splint in conformity with the part. If used as a splint it will be easily and quickly cast and cut. It can be used upon gauze and absorbent cotton, increasing their usefulness. It adheres equally well to dry and to wet surfaces, and even to very wet surfaces. The heat retained in it is hemostatic and quickly forms a dry wound.

Physiologic action: When the mixture in the bottle registers between 121 and 160 degrees C. (250 to 320 degrees F.) and is quickly removed and applied by means of a swab or brush, it will burn tissue and so produce contraction. The thickness of the layer of dressing depends upon the temperature of the mixture when applied. The hotter it is, the thinner is the layer. This temperature of 121 to 160 degrees C. (250 to 320 degrees F.) should then be used only on bleeding points and when cauterization is required. When the temperature of the dressing in the bottle registers 122 degrees C. (252.6 F.), which temperature is reached when the mixture is completely melted, its action is dessicating and hemostatic, and there is produced within a few hours a dry wound with a firm scab. As the mixture cools rapidly in transferring, the heat of it is hardly felt. When the mixture in the bottle registers 88 degrees C. (190 degrees F.) it produces no sensation and can be used as a weak hemostatic and to protect the parts. After the first layer has been spread the temperature of the mixture is immaterial. Layer after layer can be added. At 65 to 75 degrees C. (149 to 167 degrees F.) it is still adhesive, but not hemostatic, and begins to harden on the side of the bottle.

Usage. Its usage is as follows: On operative and accidental wounds. I have used it after operating for abscesses on the neck, circumcision, after removal of small tumors on the cheek, and in cases of eczema. I have applied it after accidental cuts over the head and face, in cases of crushed and fractured fingers, using it both as a dressing and a splint; on contused wounds of the scalp, on burns, upon indolent ulcers of the legs, wounds to the ears; after operations for the removal of epithelioma of the lip.

WET DRESSINGS IN SURGERY.

Presented in Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY THOMAS OSMOND SUMMERS, M.A., M.D.,
F.S.Sc., LOND.

PROFESSOR OF ANATOMY AND ORTHOPEDIC SURGERY, IN THE ST. LOUIS
COLLEGE OF PHYSICIANS AND SURGEONS.
ST. LOUIS, MO.

This may well be called the *dressing period* in the evolution of surgery. Time was when the scalpel alone was emblazoned on the escutcheon of the surgeon and with the skillful incision his responsibility ended, nor did the dignity of his office admit of his performing what then were held as the minor and menial offices of *after treatment* which then was supposed to cover everything that followed upon the first brilliant sweep of the surgeon's glittering steel. There are no doubt some who hear me today who remember

the dramatic toss of the knife behind him of the elder Gross when completing his incision and the automatic delivery of the case to his assistants for the dressing and treatment of the wound.

Even to this day the red, white and blue stripes of the barber pole tell of surgery's humble origin and the bandagers and bone-setters still roam through the villages of England and the barber surgeons still apply the leech and cup for the more dignified practitioner. It remained for Sir Joseph Lister to break the spell of *otium cum digitate*, which was the bane of all surgical progress, and teach the autocrats of the scalpel that surgery meant much more to the organism than the mere solution of continuity along anatomical lines—that this indeed was the *avant courier* of the real principle from which all the almost miraculous achievements of modern surgery had been evolved.

It was my privilege to be present at the presentation to the British Association at Edinburgh in 1875, by Professor Lister, for the first time, of a clinical demonstration of his mode of surgical dressing, which opened to surgery new worlds to conquer. The case was one of ligation of the external iliac, and the elaborate dressings being removed proved the triumph of his principle, though his venerable colleague, Professor Spence, almost on the verge of eternity, threw a well-poised Parthian lance at the rising genius of modern surgery. Since that day every operation, however simple in itself, has been one in which the surgeon "earned his bread by the sweat of his brow." No turning over the case to the unwashed student, for he whose records of success are proclaimed today is the operator who leaves not his patient until the last jot and tittle of aseptic dressing has been fulfilled, for so exacting is this principle that *falsus in uno, falsus in omni* is the inflexible law of its operation.

As a matter of course with the increase of such labor, necessary as it has proved to be to insure surgical success, the ingenuity of man was set to work at once to simplify the methods without impairing the efficiency of aseptic surgery. So active has been the work in this field that apparatus of every device and design has been offered to the profession until its name is legion, and of making of dressings as the patriarch said of books, "there is no end." As in everything else the element of "fadism" or surgical "fashion" has been dominant even in this unesthetic field, and the very men who pretend above all others to condemn the follies of feminine fashion are themselves afraid to say their soul is their own when it comes to operating and dressing of wounds before their lynx-eyed professional rivals. For years past, for example, it had been almost as much as a surgeon's name was worth to apply oleaginous preparations to surface lesions, although the very first treatment of wounds of which we read recommends the "pouring of oil," and in the case of the good Samaritan received the endorsement of the Great Physician himself.

There are some things however that fashion can not forbid, and this is one of them; like Banquo's ghost "it will not down." Long before science had thrown its searchlights over the dark field of biogenesis, experience had taught the steel-clad warrior the virtues of Gilead's balm, and from the shades of Olivet, where fell the tears of Him who came for the healing of the nations, man had learned to gather the oil for his wounded body. Since the discovery of the bacteriologic processes of infection in open wounds there has been a gradually growing tendency to return

to the ancient remedial agents which experience dogmatically taught were rationally indicated. In the last edition of that eminently practical work upon surgery, by Wyeth of New York, we find this positive and significant utterance upon the use of oil and balsam, the first surgical dressings known to humanity: "I know of nothing equal to this valuable preparation. The oil acts in a two-fold way; the surface of the wound is moistened by it, while the liquid excretion from the wounded surface is carried off in the dressing by capillary attraction. The removal of moisture cripples the proliferation of the bacteria and in this way aids in antiseptis."

In the process of repair all the structural elements must be supplied from beneath the surface of the lesions so that the constructive metabolism would not be injured by the mechanical interference of the oil globules which, as intimated in the quotation just made, would "cripple the proliferation of bacteria," which comes from without. There are many wet dressings, which if frequently renewed show excellent results, but there are few cases which come before us in which disturbance of dressing does not do mechanical injury to the process of repair, besides exposing the wound to the entrance of pyogenic and other cocci while the dressing is being changed, while the retention of material which has expended its aseptic influence is a constant menace to the integrity of the organism at large. Lister was working to the overcoming of these difficulties when he devised his "paste" dressing, which however failed to meet the desired ends in many cases. The use of animal and vegetal oils is also open to the objection offered to solutions in dressings—the necessity of changing the dressings too often—but for a different reason, the tendency of the oils to become rancid: and this applies also to the keeping of such dressings prepared for use. Wyeth recommends in his oil and balsam dressing the sterilization of the oil before using, but admits that this is often impracticable and recommends in this case the use of plain, cold castor oil of the shops.

It is therefore clear that to carry out the idea of a practical dressing it must be:

1. Antiseptic. This applies not only to the effect of the application to the part affected, but to the corporate substance itself, thus insuring it against auto-infection before applying.

2. Permanent. This is necessary in order to avoid too frequent removals as well as to preserve itself from deterioration.

3. Non-irritating. There is nothing more delicate, more easily disturbed than the formative principles of tissue, so that care must be taken in the dressing of all lesions of surface lest the agents used should arrest the tender process of repair, as well as protect it from the invasion of destructive germs.

4. Constructive. While the majority of lesions, especially those of traumatic origin, if not interfered with by destructive germs, will heal rapidly of themselves, there are very many which require not only this negative condition but also a positive stimulation of function in the constructive elements of the part. Stimulation of cell growth however must not go to the extent of irritation, in which case there will be destruction instead of construction of tissue.

The fulfilment of these conditions has been the aim of the surgical pharmacist from the time when the first coccus wriggled across the field of the microscope and gave its first exhibition to the scientific investi-

gator of its dance of death within the organism of man. But amid all this elaboration of apparatus it was to Sir Astley Cooper, after all, that the credit is due for his foreseeing therapy, leaping over as it were the dark chasm which separated the triumphs of his surgical pathology. It was he, who without the knowledge of the bacteriologic factor in the great problem of surgical treatment, by the intuition of genius gave to us the essential principles of external dressing for surface lesions. His formula, however, was open to the objection of violating one of the conditions herein laid down, that of permanence, in that lard was used instead of petrolatum, which has been since discovered, and is now substituted in the preparation known as unguentine, which is an ideal formula constructed along the lines of that suggested by Sir Astley Cooper but altered to the conditions of modern aseptic surgery. The irritating effects of the ordinary alum has also in some way been obviated, furnishing thus a typical dressing for surface lesions. For internal lesions that are to be immediately and permanently closed beneath the sutured integument, there are many valuable aseptic liquid preparations which we prefer to the too indiscriminate use of iodoform, *aristol et id omne genus*, but we are free to admit that for all external dressings we have found the highest fulfillment of modern aseptic or antiseptic surgery in the preparation just mentioned.

I am not sure whether this is a proprietary preparation or not, but this I do know, its formula is an ideal one and its results are certainly very satisfactory. It is about time we were looking around after labor-saving methods when we have to employ at the simplest incisive operations an extra attendant to wipe the sweat from our brows, as the houri fans the Sultan's heated cheek, though our attendants are not all houris nor are our cheeks fired with the congestion of a lazy passion. We are glad to see this unholy war against oleaginous applications coming to an end, just as we should be also glad to see the phlebotomy pendulum point to the nadir. In surgical politics I am a middle of the road man—in *medio tutissimus ibis*.

SURGERY OF THE LUNG.

The Oration in Surgery Delivered at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Col., June 7-10, 1898.

BY J. B. MURPHY, M.D.
CHICAGO, ILL.

(Concluded from page 297.)

Carron proposed to compress the lung over tubercular cavities with the hope that the collapse of the lung would be followed by an obliteration of the cavities. MacEwen favors resection of the ribs to allow the contraction of the chest over small cavities and the drainage and even curettement of large ones. Coromilas, Greece, favors pneumotomy and early surgical interference in tubercular processes.

If the adhesions be firm and the parietal and visceral layers can not be separated, then the parietal layer should be separated from its costal attachments and allowed to sink in with the lung, or it should be held compressed by a tampon beneath the flap for forty-eight to seventy-two hours. Will found that in thirty-six cases of tuberculosis in the early stage, thirty-two admitted of complete collapse of the lung and four only partial. If on examination it be found that the lung is free from adhesions, or that circum-

scribed adhesions exist, then the treatment is entirely different; the lung may be forced to collapse by the injection of a fluid which is slowly absorbed, as the mineral oils, alboline, etc., or better still, it may be compressed and retained compressed by the injection of nitrogen gas, after the method described for the determination of pleuritic adhesions. That this method is practicable, as far as its technique is concerned, I have demonstrated in the following cases. It can be given with little more pain than a hypodermic injection. The patients suffering from tuberculosis of the lung on whom I used this treatment are progressing favorably. We have had no postmortems to show the reparative effect upon the tubercular process. The radiographs show distinctly that the lungs remain compressed. The X-ray is of inestimable value in studying pathologic processes of the lung, particularly in the localization of cavities (see radiographs Nos. 5, 6 and 7). The degree of compression of the lung can be photographed and the rapidity of absorption of gas estimated by comparison of pictures (see radiographs Nos. 8 and 9). The outline of adhesions when gas is injected is pictured on the plate (see right side of radiograph No. 10). The following histories illustrate the method of injection and its effect:

Case 1.—Charles K., age 23, Cook County Infirmary, was admitted to the hospital April 30. He had suffered from tuberculosis of the right apex since November, 1897. Physical signs showed that it extended down to the lower margin of the third rib; there was no evidence of a cavity; tubercle bacilli were found in the sputum; patient had been coughing for three months; this was so frequent and persistent that he could not sleep. His temperature on the evening of his admission was 102 degrees. He had been having night sweats, was somewhat emaciated, and his appetite was poor. It was decided to immobilize the lung. One hundred and twenty cubic inches of nitrogen gas was injected in the sixth interspace after the method described above. The lung collapsed and he presented all of the signs of pneumothorax. The heart was displaced to the left five-eighths of an inch. The patient's breathing while on the table was a little rapid and the effort somewhat labored. He was up and about the room in five minutes and stated that he felt no distress whatever from the treatment. His cough was almost immediately relieved; he slept the following night without a coughing spell; during the day there was a superficial coughing effort to "clear the throat," as he expressed it. Eight days after the injection he came to my office and I examined him and found that the pneumothorax still existed. There was a small area of emphysematous crackling in the neighborhood of the puncture; distant tubular breathing could be heard; the patient's temperature had lowered to 99.7 degrees in the evening and was usually below normal in the morning. I had a radiograph of his chest made at this time. (See radiograph No. 8. Left side of plate was defective.) I have seen this patient every week since and his condition continues good. The last radiograph shows that but a very small quantity of the gas had disappeared, which I believe has escaped into the cellular tissue of the chest wall, as the area of the emphysema has increased.

Examination July 8. The pneumothorax had not diminished in the least. There was not a respiratory sound on the right half of the chest. The hepatic dullness was down almost to the margin of the ribs; the intercostal spaces bulged; there was a tympanitic percussion note over the right half of the thorax; the pulmonary quiescence was still complete. The patient had not coughed or expectorated a particle in five weeks; eats and sleeps well. He had had no fever and his temperature at 4:30 today is 98.2 degrees. He had not been weighed, although he feels that he has gained in weight. It is two months and a half since the injection was made and the quantity of gas is practically the same, showing that the absorption of the nitrogen is extremely slow indeed, if any of it is removed by that process.

Dr. Alexander C. Weiner and Dr. James G. Berry examined this patient with me.

Case 2.—E. L., male, age 34, Cook County Infirmary, was in the second stage of phthisis, with cavity in right upper lobe. Endeavor was made to fill the right pleural cavity with gas, but as adhesions were found it could not be accomplished.

He was not in condition to withstand operation for compression of the chest wall. The gas entered the cellular tissue of the chest and remained there three weeks, showing how slowly it is absorbed.

Case 3.—H. A. E., male, age 30, Alexian Brothers' Hospital, admitted May 10, 1898. Family history shows several cases of tuberculosis. His cough and fever began about Oct. 1, 1897. Cough very severe, expectoration limited. Night sweats since January, 1898. There were physical signs of apical tuberculosis on the right side; patient gave no history of pre-existing pleurisy; he was placed on the table, trocar inserted in the sixth intercostal space, anterior axillary line and two hundred cubic inches of nitrogen gas was injected after method described above. It was found when the trocar entered the pleura that it required no pressure to force the gas into the pleural cavity. It produced very slight coughing and but little anxiety to the patient from shortness of breath; the pulse was increased in frequency to 96 and the lips were discolored a light blue; the apex beat was displaced one inch to the left, the hepatic dullness three inches downward; the respiratory sounds entirely disappeared on the right side; respirations were increased to 26. Patient was removed to his bed; thirty minutes later was sitting up in bed eating his dinner; he said "he felt a binding in the chest and a tickling sensation in the throat;" he remained in bed for two days, as his respirations were a little increased in frequency and he complained of some discomfort in the epi-sternal region. Radiograph No. 11 shows the compression of the right lung. Examined May 20. The respiratory sounds still absent; the cardiac displacement continues; there is still absence of the hepatic chest dullness; his respirations are normal and his cough has disappeared; no expectoration.

June 30 patient presented himself again for examination; he thought his breathing was still a little short. Cough has entirely ceased; he has had no night sweats; has gained ten and one-half pounds in three weeks; his appetite is excellent.

Physical examination: The respiratory sounds are returning, though still distant; there are no rales; the percussion note shows that the chest has still a considerable quantity of gas, the liver dullness is absent down to the margin of the eighth rib and the apex beat is in about the normal position. The mediastinal dullness is to the left of the margin of the sternum; there is some bulging of the intercostal spaces, though not so marked as in previous examinations.

Case 4.—P. C., male, age 23. Admitted to Alexian Brothers' Hospital six weeks ago. Patient was in second stage of tuberculosis of the right lung. May 12 an effort was made to inject the gas in the usual manner, but adhesions prevented the admission of the gas.

Case 5.—Alexian Brothers' Hospital, E. D., May 12. Patient in first stage of tuberculosis in the right apex; has had cough, expectoration, night sweats and fever since August, 1897; bacilli in the sputum; had frequent attacks of pleurisy. Method of injection of gas the same as in case 1. Puncture made in sixth intercostal space, mid-axillary line. When parietal pleura was penetrated the gas readily passed into pleural cavity; seventy cubic inches were injected. Physical signs of pneumothorax rapidly appeared; liver dullness displaced downward one and one-half inches; apex beat displaced one-half inch to the left. Patient said he felt "his breath was shorter." The opening was sealed. In one-half hour the patient said he felt no inconvenience whatever from the injection, and was walking about the ward. He left the hospital a few days following his injection on May 12. I did not see him again until he presented himself for examination June 30. He was greatly improved in appearance; there was a slight cough, but no expectoration; he had gained in weight; his appetite was excellent.

Physical examination showed that there had been some absorption of gas, although a tympanitic sound was distinctly present over the former area of liver dullness. The respiratory sounds were feeble; there were no rales. Seventy cubic inches of gas was injected in the usual manner. It did not produce the slightest discomfort. After the injection the liver dullness was displaced almost to the costal arch. There was no displacement of the heart. There was some bulging of the intercostal spaces. Patient left the hospital immediately for his home.

July 7, at Alexian Brothers' Hospital two cases of apical tuberculosis were injected; in one 75 and in the other 80 cubic inches of gas was used; in neither was there the least discomfort from the insertion of gas; in a third case adhesions were found, making it impossible to succeed in the injection. The cases in which I believe this method

most practicable are apical or monolobar tuberculosis in the early stage, as the pathologic conditions are such that the compression of the lung can be accomplished and adhesions are not likely to be found. I do not consider that it is indicated nor practical in advanced nor chronic tuberculosis, as the fibrous tissue deposited in the lung will not permit compression of the lung, nor will the pleuritic adhesions allow of gas injection. So far no conclusion can be drawn as to the ultimate result of this treatment. Theoretically its dangers may be: *a*, hemorrhage from wounding the intercostal vessels; *b*, injecting gas into the intercostal vein, the possibility of which I question; *c*, infection by the use of impure gas, infected trocar or improper antiseptic preparation of chest; *d*, rupture of infected foci into the pleural cavity through compression of lung and separation of pleuritic adhesions; *e*, dyspnea from the use of too large quantity of gas; this can be readily relieved by changing the direction of the current in the siphon; *f*, puncture of the lung with the canula. This will not take place unless adhesions are present, and if the lung should be punctured it is a matter of no consequence, as experiments and clinical experience show that the lung can suffer great traumatism without danger. While these possibilities of danger are mentioned, none of them occurred in my experiments. I believe the gas should be reinjected every six to ten weeks as might be deemed necessary in the individual case depending upon the amount of absorption. If the respiratory sounds return the injection should be repeated. So far I have repeated the injection in but one case.

Technic of injection.—The point of insertion of the trocar varies somewhat in the individual case. If the apex of the lung be the seat of the lesion, the trocar should be inserted below the fourth interspace and back of the mid-axillary line. The best point is in the fifth interspace at the anterior axillary line. If it be a middle or lower lobed tuberculosis, the injection should be made over the upper lobe, preferably in the third interspace just outside the mammary line. The chest wall should be thoroughly cleansed and rendered aseptic. Chlorid of ethyl should be used for local anesthesia. A tenotome puncture should be made through the derma; this allows the trocar to be easily inserted. The stilette in the trocar should be withdrawn when the rib is reached; the gas should now be turned on; the trocar should then be pushed inward, hugging the margin of the rib. When the parietal pleura is punctured the trocar advances rapidly and the gas begins to flow freely into the cavity unless adhesions exist. If adhesions be present the gas will not flow. The trocar should be taken out and inserted in the same manner in another position.

The quantity of gas to be injected will vary considerably and should range from 50 to 200 cu. in.; the amount to be given in each case will be regulated by the symptoms—distress, dyspnea and the displacement of the mediastinal contents and diaphragm. The respiratory sounds on that side should be suppressed unless too great dyspnea is produced. If the patient's discomfort is great the current of gas can be reversed until relief is obtained. The trocar should then be withdrawn, the wound sealed with collodion and a moderately firm cotton compress placed over the puncture. The compress is to prevent the escape of gas from the pleura into the subcutaneous cellular tissue. The lung should be kept quiescent from three

to six months or even longer, depending upon the symptoms. When the lung re-expands, if there be evidence of active tuberculosis, the injection should be repeated; also when the respiratory sounds return the injection should be repeated, that is, the quiescence must be maintained to have the treatment effectual. During the treatment the hygienic surroundings of the patient should be the most favorable; his diet should be wholesome and nutritious.

Preparation of the nitrogen gas.—The nitrogen gas used on my patients was prepared by Prof. John A. Wesener of the Columbus Medical Laboratory, in the following manner: Compressed air was allowed to pass slowly through a solution containing pyrogalllic acid and potash; this solution absorbed the oxygen, the nitrogen thus obtained was purified by washing it through potash and then through sulphuric acid; it was then collected in a rubber gas bag which had been sterilized with a 5 per cent. carbolic acid solution. It may be retained in the gas bag or stored in a small metallic cylinder.

APPARATUS.

A properly constructed apparatus should provide means for noting the escaping gas and measuring its volume in cubic inches. The appliance shown in the accompanying illustration consists of a gas bag for storing the gas, a graduated bottle in which the passing gas may be measured, and a reservoir for securing hydrostatic pressure by means of which the gas may be forced into the pleural cavity.

The measuring bottle is supplied with a three-way stop-cock, one to connect with the gas bag, one with the reservoir, and a third with the trocar. One of these stop-cocks terminates in a tube extending to the bottom of the bottle, this cock being connected with the reservoir. It will thus be seen that if the measuring bottle be filled with water and the reservoir bottle be placed slightly above it, the water may be forced into the latter by slight pressure on the nitrogen bag. After replacing the water with the gas, the former may be used as hydrostatic pressure to force the gas into the cavity.

The trocar selected is of the Emmett type, one that may be attached to the bottle before its introduction. It consists of a straight canula to which is joined at a point near its proximal end a side tube, with which the connection is made with the bottle. This tube forms a bifurcation in the lumen of the main canula. A suitable packing is closely pressed around the trocar shaft, so that when the perforator is withdrawn the point will rest within the chamber at its proximal end, forming an airtight joint. The one I prefer is No. 7, French scale.

Directions.—Fill the graduated bottle with sterilized water and close it with the three-way stop-cock, securely fastening the latter in place and closing all the cocks.

Place the reservoir or douche bottle on a box or shelf at such a height that the bottom of it will be on a level with the three-way cock in the graduated bottle. This height may be varied according to the pressure desired. Connect this bottle with that branch of the three-way cock that terminates in the rubber tube leading to the bottom of the graduated bottle.

Fill the gas bag with nitrogen gas and connect it with one of the other stop-cocks. Attach the trocar to the longest of the three pieces of rubber tubing and connect it with the remaining stop-cock. Open the two stop-cocks leading to the upper bottle and gas bag. Slight pressure on the latter will force the gas into the graduated bottle and the water from the latter into the reservoir. Continue this pressure until the gas fills the bottle down to the zero mark. Close the stop-cock leading to the gas bag and open the stop-cock leading to the trocar until a small quantity of gas has escaped, thus displacing the air within the tube. Close the stop-cock and introduce the trocar, after which open the stop-cock permitting the gas to pass through the trocar. The water pressure in the reservoir, if the trocar be properly introduced, should force the gas into the pleural cavity, the water gradually replacing the escaping gas. By watching the graduated scale the amount of gas indicated may be accurately noted.

Incision and drainage of tubercular cavities.—Phthical cavities have been recognized for centuries. Two very interesting accidental drainages of tubercular cavities are referred to by many writers on diseases of the lungs. One is the case of Pheracus, who was

suffering with disease of the lung, and believing he was beyond cure placed himself in the front of battle and received a spear thrust which opened his pulmonary cavity and restored his health. Another was a case by De Bligny, 1679: the son of M. de la Genevraye, who was suffering from phthisis, received in a duel a sword wound in the right side between the fourth and fifth ribs; there was an abundant purulent evacuation from the wound; after the accident he completely recovered. In both of these cases, which appear mythical though true, there is nothing definite known of the nature of the abscesses, Paget has placed them as tubercular. The operation for drainage of tubercular cavities received its greatest impetus shortly after the introduction of the Koch lymph, 1890, when it was considered desirable to drain the cavity to favor the exfoliation and elimination of the sequestrum sup-

may be removed over the site of the cavity and the cavity opened; this I do not consider the best practice; four to six inches of at least three ribs in the neighborhood should be removed to allow collapse of the chest wall as cicatrization and contraction of the cavity take place after drainage. The parietal pleura should be separated from the ribs before incising it. Palpation of the area aids materially in the location of the cavity; digital exploration after incision of the lung should be favored in tuberculosis. As early as September, 1873, Mosler incised the pleura and worked his way through the lung to a cavity by dilating the tissue with an artery forceps. The patient improved very much after the operation; subsequently he died of Bright's disease.⁷³ When the location of the cavity has been determined incision should be made with the scalpel: small cavities will probably be opened

Apparatus for injection of the gas.

Trocár—No. 7, French scale.

posed to be produced by the Koch lymph. Cases in extremis, as far as the tuberculosis was concerned, were operated at that time; but the operation has gradually fallen into disuse so that it is resorted to now only in particularly favorable cases. Eward, 1884, considered the drainage of tubercular cavities curative as well as palliative, but cited no cases. The greatest barrier to surgical treatment is the difficulty of diagnosis and localization of the cavity. Physical signs, as auscultation and percussion, usually indicate the cavity at a greater distance from the hilum than it really is; this is particularly true of cavities in the lower lobe. The radiograph is of great assistance in determining the location of the cavity, as can be seen in those herewith reproduced; accurate pictures should be taken before every operation. (See Radiographs v, vi, vii.) The cavity having been located and if the drainage is all that is intended a small portion of the rib

before the large one is reached; the lung can be gently retracted until the large cavity is freely incised; the hemorrhage may be controlled with a catgut suture or the surface seared with the Paquelin cautery. The cautery should not be used to divide the lung, as it prevents inspection of the divided tissues and makes it uncertain when the cavity is reached. The entire cavity should be packed with iodoform gauze, which should be allowed to remain for several days. A drainage tube may then be inserted or the gauze packing repeated. Failure to find the cavity has frequently occurred. The ultimate result of drainage of tubercular cavities has been very unsatisfactory, which might be expected from a knowledge of the pathology of the diseased stage of cavern formation. The cavities are often multiple and only one is drained by the operation, and the tuberculosis continues its usual

⁷³ Berliner Klin. Woch., 1873, xliii, p. 509.

course in the other portions of the lung. The rapidity of amyloid degeneration of other organs may be somewhat retarded by the drainage; in a number of cases pulmonary fistulae remain. In 1890 I saw Hahn do a number of these operations and subsequently use the Koch lymph; at that time he reported that from his observations the results would not be satisfactory. Sonnenberg, in 1891, reported good results from this treatment. Kecke opposed the operation and quoted six cases of tuberculosis operated by Cerenville⁷⁴ with five deaths. His personal cases were anything but satisfactory. Jaenfert⁷⁵ named certain conditions contraindicating operations on tubercular cavities: 1, tendency to hemorrhage; 2, the danger of pneumothorax; 3, drainage does not remove the original disease, and operations under these conditions give a great mortality. Truc reports 18 cases with 6 deaths within three months after the operation. Poissier and Jannesco collected 29 cases and showed 10 deaths, 15 improvements and only 4 recoveries. Hofmohl reports 5 cures after treatment of tubercular cavities by operation. Douglas Powell opposes the drainage of tubercular cavities on the grounds: 1, that the cavities are fairly well drained, situated as they are in the apex; 2, the cavities are not often single with an activity of symptoms; 3, that excavation in phthisis is a conservative process. The latter statement is misleading; true, the excavation is a conservative process, but the absorption of the products of mixed infection subsequently retained in the cavity is distinctly injurious to the entire organism; this is the principal reason for the drainage of the cavity. Patients rarely ever die from simple tuberculosis of any part of the body, and particularly from simple tuberculosis of the lung, it is the mixed infection which causes the great fatality. Tubercular cavities in the lower lobes are more easily drained, should give better results after drainage, and are more fatal when not drained than cavities in the upper lobes. The former points are emphasized by the case reported by N. Pendleton Dandridge⁷⁶ in his able article on the treatment of pulmonary cavities. While drainage of large tubercular cavities has not given satisfactory results as far as cure is concerned, I feel it is the surgeon's duty to resort to this operation very frequently as a palliative measure, as it relieves these great sufferers of their most distressing symptoms, viz.: cough and expectoration.

The following case illustrates the operation and course of cases after drainage of tubercular cavities:

J. M. C., aged 46, Cook County Infirmary, has been suffering from symptoms of tuberculosis for 10 months. He has emaciated to a great degree; has had severe night sweats, afternoon hectic flushes; he expectorates large quantities of purulent material with spasmodic attacks of coughing; one or two hours may pass without coughing, then he will get a severe spell and an ounce or more of pus will be expectorated, the odor of which is not particularly offensive. Examination reveals rales over upper lobe of right lung, extending down to the fourth rib; bronchial breathing, absence of normal respiratory sounds; a cavity can be located under the second rib, two inches to the right of the sternum, and extends from upper margin of the second to upper margin of the third rib; its transverse diameter appears to be about one and one-half inches.

Operation Dec. 12, 1897. It was decided to open and drain the cavity; a U-shaped incision was made extending from the first to the middle of the third rib, one inch to the right of the sternum. The incision was then curved upward and outward to the anterior axillary border; sub-periosteal resection of

about three inches of the second and third ribs was made; the parietal pleura was separated from the chest wall to the extent of about an inch around the field of operation; the exploratory puncture was now made for the first time and pus withdrawn. A horizontal incision was made in the pleura over the center of the cavity; adhesions were present, and the incision continued about one and one-half inches in length, until the cavity was reached, which was opened at a depth of about one inch; the hemorrhage was not profuse, and was readily controlled by pressure; a digital examination of the cavity showed that it was about two inches in diameter with an irregular surface; it was packed with iodoform gauze; there were a number of smaller bronchiectatic cavities opened in making the incision and a few caseous bronchial glands were removed from the mediastinal margin; the packing was removed in fifteen minutes; there was still some oozing, which was controlled by the Paquelin cautery. The cavity was repacked with iodoform gauze, and the flap was accurately sutured around the gauze drain; chloroform narcosis. The patient was not in the least shocked by the operation; the highest pulse rate following was 92; the temperature on the third day was 100.6 degrees; after the fifth day it did not exceed 99 degrees. He expectorated a bloody mucus for the first three days. He had no "fits of coughing" after the operation; the packing was removed on the fifth day and a soft rubber drain inserted; he was allowed to be up and about. There was a primary union of the flap except at the point of drainage. The drain was allowed to remain in for five weeks; it was then removed, as a fistulous canal had been established. His cough is reduced to a minimum, the discharge from the fistula is of a non-purulent mucous character, and while the fistulous opening is large the quantity of discharge is small. He has gained in weight, his night sweats have ceased, and his general condition is greatly improved. May 30, Dr. Johnson, Medical Director of the Infirmary, reports that the communication of the sinus with the cavity has closed, and that a small granulating surface remains at the external opening.

I have collected reports from the literature as follows: Tuberculosis of lung operated, 47; incision and drainage, 34; pneumectomy, 2; thoracoplasty, 5; puncture and drainage, 2; opening of superficial abscess, 4; recoveries, 26; recovery with fistula, 2; deaths, 19; 12 from undetermined causes; 1 multiple gangrenous foci; 1 acute miliary tuberculosis; 3 hemoptysis; 1 hemorrhage; 1 cachexia.

Pneumectomy for the removal of a part or a complete lobe of the lung for a tuberculous disease has been one of the triumphs of surgical technique, but so far the clinical results have been unsatisfactory. From the experiments of Gluck, Schmid, Bloch and Biondi,⁷⁷ we were led to believe that pneumectomy as a curative method for tuberculous lesions of the lung would become an accepted surgical procedure; however, our hopes have not been realized. While the operation of removal of a complete lobe of a lung has been successfully performed the number of deaths following pneumectomy has been so large that the operation has been practically abandoned. The technique of pneumectomy will be given under the heading of Pneumectomy for Neoplasms.

Kronlein in 1884 operated on two cases of apical tuberculosis; one lived but a few hours after the operation, the other but a few days. Ruggi, 1885, operated on two cases; one died on the ninth day from carbolic poisoning, and the other thirty-six hours after the operation. In 1891 Tuffier removed a small portion of the right apex through the intercostal space for tuberculosis; the patient made a good recovery and four years later was enjoying excellent health. In 1893 Mr. D. Lowson operated successfully on a woman 34 years of age for tubercular disease of the right apex. Doyen, 1895, also successfully removed a small portion of a lung for tuberculosis. Kronlein and Lowson give definite rules for the operation, the latter favoring the H or U-shaped incision, removing the second, third and fourth ribs from the sternum to the axillary line; this gives a large opening

TUBERCULAR CAVITIES—1878 to 1898.

Pleural Adhesions.	Puncture.	Incision.	RESULTS.		Necropsy.
			Immediate.	Final.	
No adhesions.	Puncture in the 7th interspace, pneumothorax and subcutaneous emphysema. 2 pints of fetid pus, lavage.		Considerable amelioration 6 mos. later.		
Adhesions.		Incision in 10th interspace without resection of rib opening of a small cavity with the finger. Drainage.	Death 14th day.		Large cavity in left base not opened.
		Puncture of cavity with trochar coarse, drainage.	No influence on general condition.	Death in 28 days after operation.	
		Thorocotomy and with forceps bored into lung, cavity was reached.	Patient died 7 days after operation.		
Adhesions.	Puncture made, blood.	Pneumotomy.	Death on 6th day.		Partial pneumothorax, a large superficial cavity in left lung.
		Incision of axillary abscess, issue of pus and gas. The liquid discharged is similar to the expectorate of the patient.	Recovery.	Recovery without fistula.	
Adhesions.		Resection of 8 cm. of 2d left rib, exploratory puncture, removal of purulent and bloody fluid. Pneumotomy, opening of cavity.	Recovery. Observation 15 days after recovery.		
		Pneumotomy, drainage, insufflation, iodine and phenol.	Death, Hemoptysis.		Purulent cavity with granular wall.
Adhesions.		Pneumotomy, discharge of pus, air and gangrenous debris, drainage.	Death 15th day. Pains increased after operation.		Bilateral tuberculosis, cavity opened.
		Thorocoplasty, resection of 5th rib to obliterate cavity which was not opened.	Death 14 days later.		No necropsy.
Pleural adhesions.	Negative puncture. Incision, trocar introduced into cavity.	Resection of 1 and 1½ in. of 9th rib just within a line drawn from angle of scapula, small drainage introduced, next day 1 oz. of pus escaped, opening dilated and several oz. of pus escaped.	Recovery.	Steady improvement since operation.	Temperature normal.
		Resection of 3d rib.	Death 15 days after.		
Adhesions.		Resection of 3 cm. of 2d and 3d ribs. Pneumotomy opening of a cavity situated behind the clavicle.	Death 45th day.		Acute general miliary tuberculosis.
Pleural adhesions.	Exploratory puncture, positive.	Resection of 2 cm. of 9th rib. Pneumotomy, a cavity the size of an orange, opened and drained.	Death 7th day.		Single cavity opened, tuberculosis of right apex more recent, tubercles in left lung.
		Resection of 6th and 7th ribs. Pneumotomy, injection of vaselin and salol.	Recovery, amelioration 4 months later.		
Left pleural firmly adherent in upper one-third.	Puncture 1 month after onset of empyema.	Thorocotomy Sept., 1886, and Jan., 1888, with resection of piece of rib in lower and hind part of thorax. In April, 1888, extensive rib resection from 2d to 6th rib on left side in front, and 7th to 9th rib, left side behind. On May 27, 1888, front of chest wall resected from 2d to 6th rib, close to the sternal border. Breadth of resection 5 cm. above and 12 cm. below, left pleura tuberculous and right lung phthisical, large as man's fist, firmly adherent at 1st rib, left lung partly covered by pedunculated skin flap.	Organs shrank after last operation and tuberculosis of lung underwent process of spontaneous cure as a result of shrinkage.	Patient discharged as cured July 23, 1888.	
No adhesions.		Thorocoplasty, cavity not opened.	Recovery.	Cured 7 mos., disappearance of signs of cavity of left apex, the right apex not operated upon, healed equally well.	
Adhesions.		Resection of 8 cm. of the 2d left rib. Exploratory puncture, removal purulent and bloody fluid. Pneumotomy, opening of cavity.	Recovery 15 days after operation.		
Pleural adhesions present.		Resection of ribs. Pleura opened with blunt instrument, lung over cavity was punctured, free opening made, cavity packed with iodoform gauze.	Fever fell after operation, considerable secretion, improvement after operation so patient could leave bed, sudden hemoptysis set in and caused death.		
No adhesions.		Incision in the 2d intercostal space, pneumothorax. Pneumotomy, injection of iodoform.	Pneumothorax absorbed in 6 days, recovery without fistula, cavity measured 12 p. m. in diameter.	Death 3 years later, general tuberculosis.	
		Rib resection. Pneumotomy, iodoform tamponade.	Death. Hemoptysis.		
		Incision at level of upper border at 3d rib. Pneumotomy without rib resection, amelioration. Injections of Koch's tuberculin.			
Pleural adhesions.		Incision in 1st interspace 7 cm. long, trocar introduced, cautery used to penetrate lung cavity size of apple, walls curetted and packed with antiseptic gauze, Koch's tuberculin injected and caused increased discharge.		Patient was much improved in general health, cavity dwindled down to 1½ its normal size.

TUBERCULAR CAVITIES—1878 to 1898.

Pleural Adhesions.	Puncture.	Incision.	RESULTS.		Necropsy.
			Immediate.	Final.	
Adhesions.	Incision parallel with clavicle, resection of a fragment of 1st rib, exploratory puncture. Pneumotomy, opening of a cavity the size of hazel nut, iodoform tamponade.	Recovery. Cavity rapidly obliterated (2 mos.) Injection of Koch's tuberculin after the operation many bacilli in the sputum.	Recovery.
Adhesions.	Parallel with clavicle, puncture. Pneumotomy, opening of a cavity the size of a walnut.	Recovery. Injection of Koch's tuberculin after operation.	No amelioration.
Adhesions.	Parallel with clavicle, puncture. Pneumotomy opening of a cavity the size of a hazel nut, 1 cm. deep.	Recovery. Injection of tuberculin after operation.	No amelioration.
No adhesions.	Resection of 4th rib. Incision of pleura. Partial pneumothorax. Pneumotomy, injection of tuberculin.	Death 7th week. Cavity opened spontaneously on 11th day through scar.
No adhesions.	Pneumotomy after suture of pleura. Opening of a small cavity. Drainage, incision made in anterior wall of thorax.	Recovery. A large cavity which could not be opened, discharged into the inside cavity 3 weeks later. Patient much improved.
Adhesions.	Pneumotomy drainage.	Recovery.	Marked improvement, drainage maintained until complete closure of cavity.
Pleural adhesions.	Anterior $\frac{1}{2}$ of 2d and 3d ribs, removed parietal layer of pleura opened, apex of lung pulled out after transfixed with needle, tied with strong silk and removed.	Pneumothorax developed suddenly but gave no trouble.	Wound was healed by end of 3d week.
Pleural adhesions.	Level of 2d intercostal space. Pneumotomy, opening of a cavity located 2 cm. deep. Hemorrhage at the moment of incision, drainage, injection of chlorin gas next day.	Death on 8th day from hemorrhage.	No necropsy.
Adhesions.	Incision in 3d interspace. Pneumotomy, opening of a cavity, drainage. Injection of chlorin gas.	Death 24th day, cachexia.	No necropsy.
.....	Superficial incision, issue of pus, of gangrenous debris and gas. Iodin injected into the wound appeared in the sputum.	Recovery.
Pleural adhesions.	Positive puncture, bloody fluid.	3 inches of 8th and 9th ribs removed in axillary line underlying cavity freely opened, $\frac{1}{2}$ pint bloody purulent fluid, caseous material evacuated, irrigations with boric and sal, skin incision partly closed, double drainage tube, tube taken out after several days. Incision healed.	Immediate improvement.	Was soon up and about house. Area of dullness diminished. Respiratory sounds heard at a lower level than before.
.....	Incision and drainage.	Recovery.
.....	Puncture and dilatation of tract, drainage of $\frac{1}{2}$ liter pus.	Recovery.	Condition satisfactory 6 $\frac{1}{2}$ mos. later, tuberculosis still exists.
.....	Pneumectomy, resection of the 3d rib.	Death occurring the night following the operation. Death in one month.
.....	Resection of 10 cm. of 7th and 8th ribs, exploratory pneumotomy, upon opening a series of dilated bronchi were found.	Tuber. right apex without cavity's, small cavity at base not opened.
.....	Resection of 7.8 cm. of 8th and 9th ribs. Pneumotomy, incision 4 to 5 cm. in depth without opening cavity.	Temporary amelioration.	Death 3 months later.	Disseminated tuberculosis in entire right lung.
Pleural adhesions.	Thoracoplasty, 5th, 6th, 7th, 8th and 9th ribs resected. Pneumotomy.	Recovery.	Much improved 3 months later.
.....	Incision in 2d interspace and ant. axilla pleural pneumo chorax by attaching parietal to viscera pleura. Piece of lung 2 cm. in all directions was excised, wound closed without drainage.	Patient up 9th day.	4 yrs. after operation patient was healthy.
No adhesions.	Incision and application of a paste of chlorid of zinc in the first intercostal space. Pneumotomy after exploratory puncture, resection of 2d rib 16 days later, many small cavities opened.	Recovery.	Death 3 yrs. later from progress of the tuberculosis.
Adhesions.	Thoracoplasty, resection of 2d and 3d ribs without opening.	Recovery.	See foot note.	Cicatrized cavity right apex, sclerotic lung cavity open'd during 2d operation is recent. Sclerosis of left apex. Enorm's sterno-costal cold abscess, communicating with the cavity opened by a narrow orifice. Right lung almost completely destroyed, left lung studded with tubercles.
.....	Incision and resection of 6th rib in axillary line. Puncture, discharge of pus containing bacilli, lavage, drainage.	Death 1 month later.
Adhesions present.	Puncture at lower dull area, negative, a 2d puncture at higher and deeper point revealed pus.	Pneumotomy. U-shaped incision 3 $\frac{1}{2}$ inches between 7th and 8th ribs and anterior axillary and scapula lines resected, pleura opened. Pleural cavity shut off with gauze, lung incised with cautery to depth of 1 and 1 $\frac{1}{2}$ inches, 75 cubic cm. of thick non-fetid pus escaped, opening enlarged and cavity swabbed and packed with gauze. Gauze removed from pleural cavity skin and muscle flap sutured.	Improvement, temperature lowered.

Cure maintained 1 year. Closure of cavity, relapse and reappearance of the signs of cavity in right apex. 2d operation, resection of 2d, 3d, 4th and 5th ribs. Pneumotomy, dressing compression. Death 28 days later from emphysema and accidents produced by the chloroform.

through which to work. After the chest has been opened the lung is to be drawn out, transfixed, ligated and amputated with the cautery. The cavity should then be drained and only partially closed. Tuffier in his operation deviated from this by producing an extra-pleural pneumothorax before opening the parietal pleura; he then divided the pleura and drew the diseased portion out through the opening. He closed the wound completely; his patient was about in twelve days. He places particular stress upon the advantage of preliminary extra-pleural pneumothorax. The pathologic conditions which render this operation necessary are such that at a time most favorable for the performance of the operation the patients will not submit, and when they desire the operation the pathologic changes are so far advanced that they are not in condition to withstand its severity. In one attempt at this operation adhesions were found so firm and resisting that the operation had to be abandoned. The dangers of separating an adherent apex on the mediastinal side should be borne in mind; 1, the mediastinal septum in front is thin and easily lacerated; 2, there is danger of tearing the azygos veins and the subclavian artery or vein at the extreme apex; 3, lower down there is danger of tearing the right cardiac auricle; this accident happened to me in an operation on the cadaver. When the lung is in an advanced stage of tuberculosis its infiltration is so extensive that it is not compressible, and estimates on its removal must be based on the principles governing removal of a solid tumor of equal size. I have found when placing the forceps or ligature on the lungs of cadavers in this condition, that many times the tissue lacerated with the pressure. It must therefore be understood that the ligature must be placed on the base of the lobe, including only the arteries, veins and bronchi, and that the opening must be sufficiently large to admit of the extraction of a solid mass the size of the lobe to be removed. The removal of a complete lung for tuberculosis has not to my knowledge been attempted. In advanced tuberculosis the pathologic changes produce insurmountable barriers against the operation of pneumectomy, and while occasional success in partial resection may be achieved it can never become a practical method for the treatment of tuberculosis. I believe the trend of surgery in tuberculosis of the lung will be the utilization of surgical means for placing the lung in better condition for repair, as quiescence, compression, drainage, etc., rather than extirpation of the tubercular focus.

Hydatid cysts.—The surgery of hydatid disease of the lung is well established and exact lines are drawn as to its operative treatment. The results have been very flattering to the surgeon. It is variously estimated that from 11 to 16 per cent. of hydatids of the body occur either in the pleura or in the lung, these situations being the most frequent next to the liver. Many of the cases are secondary to disease of the liver, as the following case illustrates:

J. L., male, aged 46, came under my observation November, 1884. Six weeks previous he complained of a sudden pain in the right side, followed by dyspnea and a dry hacking cough; the distress was severe for three days; a diagnosis of pleurisy had been made and he was placed under medical treatment; when he presented himself at my office the following conditions were found: Respirations 36, temperature 99.2 degrees, pulse 110; he complained of great compression in the right side; dullness extended to the spine of the scapula behind and to the second interspace in front; respiratory sounds were absent; there was a bulging of the intercostal spaces and the apex beat

was displaced one inch to the left; the liver margin extended one and one-half inches below the costal arch. The edge of the liver was soft and pliable and of regular anatomic formation.

Diagnosis.—Hydrothorax; aspiration of a large quantity of clear fluid; microscopic examination revealed hooklets. Patient had temporary relief, but in three weeks the distress was as great as before, when an operation was advised.

Operation.—Resection of two inches of the ninth rib in the anterior axillary line; a large quantity of fluid escaped; an opening in the diaphragm could be felt about two and one-half inches from the costal margin. A perforated drain was inserted through this opening and brought out through the chest wall. The patient improved rapidly in his general condition. Four weeks later there was a free discharge of bile through the tube. The pleural cavity rapidly contracted and at the end of three months there was nothing but a sinus into the liver, which was discharging bile freely; the tube was removed in five months; bile continued to discharge in enormous quantities; the sinus closed nine months from the time of the operation; the patient has remained well up to the present time.

In the United States hydatid is infrequent; it is often met with in the Canadian provinces and particularly among the Finlanders (A. H. Ferguson). The mortality from the disease treated medicinally or without treatment has been variously estimated; Niesser places it at 58.7 per cent; Devaine, 66½ per cent.; Thomas, 54 per cent. The great majority of cases that recovered without surgical aid ruptured into the bronchi, and a few externally.

There are three methods of external treatment: 1, puncture; 2, free incision; 3, removal. Maydl collected sixteen cases treated by puncture, of which 69 per cent. died. The dangers of puncture are: 1, drowning during operation by opening into bronchus; 2, emphysema; 3, dyspnea from pneumo- and hydrothorax; 4, albuminous edema of the lung. The fatal accidents of puncture of hydatids must be borne in mind, and in hydrothorax when hydatid is even suspected exploratory puncture must not be performed; as an incision has no more dangers than puncture in simple hydrothorax and is so very much less dangerous in hydatid cyst, it should be adopted in place of puncture in doubtful cases. Puncture with canula is curative in only 25 per cent. (Tuffier); as the canula becomes occluded the multiple cysts are not drained, infection takes place and the incision will eventually have to be resorted to. Tuffier gives the immediate mortality of puncture with canula as 50 per cent. Thomas, 1885, gives the following comparison of results: Hydatids of the lung and pleura not interfered with had a mortality of 54 per cent.; treated by puncture, 27 per cent.; treated by incision and resection, 16 per cent. Schwalbe (l. c.) states that hydatids of the lung without operation have a mortality of 60 per cent. Lopez collected thirty-six cases treated by pneumotomy; the mortality was 14 per cent.

Suppurating hydatids communicating with the bronchus, if not progressing favorably, should be treated as pulmonary abscesses, opened and drained, after fixation of the lung to the thoracic wall. Roswell Park collected thirty-two cases with four deaths, a mortality of 12.5 per cent. It is claimed by Tuffier that 90 per cent. of the cases recover after pneumotomy.

Tumors, from 1884 to 1896.

Case 1, 1884. Kronlein Berliner Clin. Chir. Woch., 1884, p. 199, and 1886, p. 185. Correspondenzblatt Schweizer Aerzte 1887, xvii, p. 696, et in Mueller Deutsche Zeith. für Chirurg., 1893, Vol. 67, p. 41. Female, 18 years. Diagnosis: sarcoma of lung secondary to costal sarcoma of eight months' standing, in sixth rib, left axillary line. Operation in thorax pleura: incision from second to fifth rib, resection of thoracic wall, fifth, sixth, seventh and eighth ribs being found adherent to tumor; once adhesions are separated there is produced an alarming thorax; anesthetic had to be stopped. Operation on lung extirpation of secondary sarcomatous nodule the size of a walnut; resection done in healthy pulmonary tissue, lung sutured with catgut, drainage of pleural cavity; recovery without incidents. Results: recurrence without scar three years and three months

after extirpation and pneumectomy, recurrence six months after in thoracic wall, new operation but no pneumectomy; died seven years after first operation; general metastasis.

Case 2, 1887. Sedelot, quot. Baldus in 1887, Bown, p. 16, et Par. Mayer-mang, dissetat, 1889, p. 13. Diagnosis: sarcoma of lung secondary to sarcoma of thoracic wall. Operation in thorax pleura: resection of two ribs and all of thoracic wall, including pleura. Operation on lung: resection of portion of lung adherent to thoracic wall. Recovery.

Case 3, 1893. Mueller, Deutsche Zeitsch. für Chirurg., 1893, Vol. 37, p. 42. Male. Diagnosis: chondroma of lung secondary to costal osteo-sarcoma, four years; base of right lung and anterior portion of thorax from sixth to seventh ribs and from sternum to axillary line. Operation in thorax pleura: resection of thoracic wall from third to sixth ribs, inclusive, adhesions of lung to pleura being separated there is produced a complete pneumothorax with cessation of respiration; these symptoms ceased on lung being drawn to thoracic wound. Operation on lung: extirpation of neoplastic nodule, double ligature of pulmonary pedicle and suture of lung wound, which measures 9 by 13 cm.; drainage of pleural cavity. Rapid recovery in three weeks; superficial recurrence in scar two years and three months after extirpation; patient is still cured, four years and eight months after first operation.

Case 4, 1894. Weinlechner in Mueller Deutsche Chirurgie, xl, 2, p. 269, in Mueller Deutsche Zeitsch. Chirurg., 1895, xlvii, p. 41. Diagnosis: myxocongroma of lung second to myxocongroma of thoracic wall. Operation in thorax pleura: resection of three ribs and of all thoracic walls, including pleura, resection of portion of lung as large as the palm of the hand adherent to tumor, resection of two pulmonary metastatic nodules in inferior lobe. Death twenty-four hours after. Necropsy: purulent pleurisy, excision of thoracic walls had not allowed union of soft parts.

Case 5, 1896. Koenig, Berlin Wech., 1896, p. 132. Diagnosis: sarcomatous nodule secondary to sarcoma of sternum. Operation on thorax pleura: resection of sternum. Operation on lung: resection of small sarcomatous nodule without suturing pulmonary wound. Died on night following operation of a pneumothorax.

Case 6, 1896. Williams, quot. by Zegari, p. 143. Male, 37 years. Diagnosis: myxocondroma of median lobe of right lung, secondary tube costal myxocondroma; duration four years; from second to seventh ribs in neighborhood of nipple. Operation in thorax pleura: resection of thorax of third, fourth and fifth ribs, pneumothorax, collapse of lung. Operation on lung: resection of a voluminous nodule of small volume in superior lobe; death due to collapse.

Actinomyces of the lung.—Actinomyces of the respiratory organs is next in frequency to actinomyces of the digestive tract. It may appear as a primary lesion of the lung, or the lung may be secondarily attacked from an actinomyces of the bony framework of the chest or from an actinomyces penetrating the diaphragm. A detail of the history of the disease, while it might be very interesting, will not be considered here. Langenbeck in 1845 first described the disease. Ponfick, Israel and Bollinger made a very extensive study of the subject. Israel collected nine cases of actinomyces of the air passages. When it occurs primarily in the lung it may have been inhaled. When the lung is infected the tendency is to a rapid infiltration and extension of the disease. It is not so likely to be overlooked now as in former years; the sputum of every patient with chronic pulmonary lesions is repeatedly examined, and while the ray fungi are not sought, they are not often overlooked. The medical treatment of actinomyces is becoming more satisfactory as time advances; iodid of potassium has proved most useful. We find in the literature a number of cases in which it was used with curative effect; it should be administered in increasing doses until iodism is produced. This is now being supplemented by the internal use and external application of nitrate of silver, suggested by Dr. Poore (Paget). He bases his recommendation on his experience in one case of actinomyces of the right pleura and the specific fatal effect of nitrate of silver upon the aspergillus niger noted by Raullins; one part in a million and a half in culture media would prohibit the growth of the latter. When the lung is infected with actinomyces it produces no specific symptoms in its early stage; later the chest wall is attacked and external sinuses may develop, when the true character of the lung lesion can be readily recognized if it has not already been detected in the sputum. If treated surgically the indication is a radical extirpation of the disease; if this can not be accomplished, careful and thorough curettement and packing with a nitrate of silver gauze is indicated. Godlee favors radical surgical treatment when iodid of potassium has failed, and while I agree with him in this *dernier ressort*,

from my experience with surgical treatment of actinomyces in other parts of the body, I would consider that the lung is a very unpromising field for surgical treatment. A very interesting case was reported by Dr. Karewski at the recent meeting of the Berlin Medical Society.⁷⁸ Fraenkel made the diagnosis from the physical appearance without the aid of the microscope; extensive resection of the ribs and chest wall was made; the patient recovered and only a small sinus remained.

Dermoid cysts will not be considered in this article, as they are always mediastinal tumors and not true tumors of the lung, although they frequently rupture into the trachea or bronchi and their contents are expectorated (see Clotta's case, also a very interesting case reported by Dr. Ogle;⁷⁹ another by Rickman J. Godlee).⁸⁰ These tumors are all of mediastinal origin (Bland Sutton).

Neoplasms of the chest wall and lung requiring pneumectomy.—Of the neoplasms occurring primarily in the chest wall and involving secondarily the pleura and lung we may mention, 1, the sarcomata of the ribs and sternum; 2, the enchondromata (varieties); 3, the carcinomata, occurring first in the mammary gland and involving the muscle, bone and pleura of the chest wall by continuity of the process or by secondary glandular infection. The following tumors in the lungs are pathologic curiosities: Fibromata, lipomata, angiomas, dermoids (Clotta) and gummata of the chest wall. When these neoplasms invade the pleura, adhesions are not infrequently formed; the lung may also be involved at the time of operation, necessitating excision of a greater or lesser portion of it with the tumor. Primary malignant neoplasms of the lung are rare; secondary involvement of the lung by carcinoma and sarcoma is not uncommon. Wilson Fox, who collected 112 cases of tumors, showed that the disease was primary in 38, secondary in 64 and indetermined in 10. Primary cancerous growths usually originate in the mucous glands, and as these are lined with cylinder cells they are frequently cylindrical epithelioma. An alveolus may be the initial seat of the disease. Primary sarcoma may occur in the lung and is usually of the round-celled variety; spindle-celled and myeloid growths have been observed; they very closely resemble aneurysm and the greatest care must be exercised in making a differential diagnosis. In many cases it is difficult to say whether the malignant disease is primary or secondary in the lung; the surgeon is rarely called upon to operate on these cases, as they are not diagnosed. The class of malignant disorders of the lung which comes to the surgeon for operation is that in which the disease is secondary to disease of the chest wall. This leads us to the consideration of the subject of pneumectomy in general.

Pneumectomy was performed first for the cure of hernia of the lung; one case was published by Rolandus, 1492. The cases of amputation of a protruding lung do not clinically come under the heading of pneumectomy, as they do not involve the dangers and difficulties of technique associated with intra-thoracic pneumectomy. The first pneumectomy was made by Péan in 1861: he was resecting a tumor involving the third, fourth and fifth ribs; the pleural cavity was opened, the ribs mentioned excised and the lung was

⁷⁸ Allgem. Med. Centr. Zeit., Vol xxiii, xxiv, p. 298.

⁷⁹ Medical Week, Paris, March 5, 1897, p. 101.

⁸⁰ Ibid.

found adherent and involved in the tumor. The visceral and parietal pleura were sutured and the Paquelin cautery was used to remove the diseased portion of the lung. The first scientific experimental investigation was made by Gluck, 1881 (l. c.). He performed pneumectomy on 6 dogs and 14 rabbits; two of the latter lived for three months; all of the dogs died; in one, in which he ligated the stump of the lung without a pneumectomy, he found that the portion of the lung on the distal side of the ligature did not mummify, but lived. There was primary union of the vessels. There was always immediate cyanosis after the operation. He arrived at the following conclusions: Ligature with pneumectomy is tolerated well by rabbits; if the operation be aseptically and well performed recovery is permanent; primary adhesion of vessels takes place; no cardiac thrombosis; the stump lives and forms part of the cicatrix; the fatality is caused by pneumothorax, pericarditis, infective pleurisy of the same and opposite sides. Milton Antony⁸¹ of Augusta, Ga., reports that in 1821 he was called to a patient in the western frontier suffering from a growth of the lung pressing out the fifth and sixth ribs. He made a resection of these, scooped out the degenerated tissue or tumor of the lung and plugged the cavity; the patient recovered. While this case antedates Péan's it should not be considered a pneumectomy. From his report there is some doubt that any lung tissue was removed, as the patient had no cough nor expectoration and there was no mention made of air escaping through the wound. Be that as it may, he deserves credit for having suggested and practiced sub-periosteal resection of the rib to allow the wall of the chest to fall in and fill the space; an operation which subsequently added much to the fame of Estlander and Schéde. Marcus, in 1881, removed one entire lung from two dogs and three rabbits. One dog died from the anesthetic, the other from purulent pleurisy; the rabbits died on the third, sixth and twenty-seventh days respectively. These experiments were rapidly followed by those of Hans Schmid,⁸² which were made independent of a knowledge of Gluck's. He used morphin and ether for narcosis; hemostasis of the excised portion was secured by transfixion and ligation with catgut; he made exact suture of the edges. In eight partial resections in dogs there were five deaths and three recoveries; the deaths were caused in four by suppurative pleuritis, in one by carbolic acid poisoning. In partial resections a V-shaped incision was made with accurate suture of edge. He removed both apices successfully in the same dog, six weeks intervening between the operations; there was no secondary hemorrhage; he expressed the belief that partial excision was applicable to local tuberculosis, injuries, abscesses and tumors of the lung and rib.

In May, 1881, Bloch performed nine experiments for the removal of the lung on five rabbits and four dogs; all of the former died immediately after the operation; one of the latter lived fourteen days; the other dogs all died shortly after the operation. In July, 1881, he performed sixteen experiments with resection of the rib on rabbits; all died a few days after from hemorrhagic pleurisy; the time required for operation was forty-five minutes. He changed his method to an intercostal incision with the removal of single lobes and reduced his time to ten minutes.

With this method two dogs recovered, one from a lower and the other from a middle lobe amputation; when the dogs were killed no pneumothorax, exudate, nor displacement of organs was found. He noted the anatomic communications of both pleural cavities in some dogs; all with this communication terminated fatally; he advised against drainage. He removed infiltrated lobes through intercostal spaces and favored that plan very much.⁸³ Bloch's experiments were very discouraging, but the profession was soon relieved from their depressing effect by the more extensive, scientific and fruitful researches of Biondi which carried the profession too far in the opposite direction. In 1882 Biondi made the following experiments: Extirpation of right lung, healthy animals, 23 experiments, 12 recoveries; extirpation of left lung, healthy animals, 34, 18 recoveries; extirpation of both apices, 3 experiments, 3 recoveries; middle lobe, 1, 1 recovery.⁸⁴ His experiments were exact as to details and his results were the best obtained. He found that the great majority of animals infected artificially with tuberculosis in the lung and not treated died of the tuberculosis; on the other hand, he found that a timely resection of the apex of the lung saved a goodly number. The success of these experiments stimulated surgeons to operations for removal of the lung. Zakharchewitch made a minute study of the technique of these operations experimentally on cadavers and on animals. His results almost equalled those of Biondi. He laid down definite rules for pneumectomy. W. LeMoyné Wills⁸⁵ reports some very interesting and instructive experiments of pneumotomy and pneumectomy.

Weinlechner, in 1882, removed three ribs for malignant disease and excised two nodules from the lung; the opening in the pleura was so large that he found it impossible to obtain a sufficient flap to cover it; closed with packing: patient died in twenty-four hours from acute pleuritis.

Kroenlein, in 1884, operated on two cases; one ended fatally a few hours after operation and the other lived but a few days. Ruggi, in 1885, performed two operations; in one he succeeded in removing the apex, and the patient died on the ninth day from carbolic acid poisoning; in the other he found it impossible to detach the lung from the pleura; the patient died thirty-six hours after the attempt.

Sedillot, in 1887, removed a portion of a lung which was adherent to and involved in a sarcoma of the chest wall. Patient recovered. W. Miller, 1888, removed a portion of lung and chest wall successfully for enchondroma.

In 1891 Tuffier removed successfully a tubercular nodule from the apex of the right lung. He first separated the parietal pleura from the ribs all around the field of operation; when this was accomplished he palpated the tumor, divided the pleura, grasped the lung with the forceps and drew it out through the slit in the pleura, producing a hernia of the lung. A tubercular nodule the size of a hazel-nut was excised and the lung was allowed to drop back. The incision was completely closed; the patient was reported well four years later. This was certainly an ideal case for excision.

D. Lowson, 1893, excised the apex of the right lung for tuberculosis. He made an angular incision and resected the second and third ribs. A small opening

was made in the pleura; he filled the pleural cavity with sterilized air to force collapse of the lung. This caused no dyspnea or cyanosis; he then opened the pleura, freed the adhesions and brought the lung out through the fissure, transfixed it, ligated and excised the infiltrated portion; he replaced the lung and closed the chest cavity without drain. It had to be opened two weeks later for the removal of some pus and blood; the patient was discharged from the hospital in eighty days; she had gained rapidly in flesh and the wall was closed to a small sinus. This operation shows the most praiseworthy preparation and execution, and the result was well deserved.

These operations were rapidly followed by those of Miller, Koenig, Mikulicz, Albert, Tillmanns and others; but the hope of success that was born from the results of Biondi's experiments has never been realized. In 1887 Roswell Park, in an able article, reviewed the cases treated up to that time. E. Willys Andrews⁵⁶ advocates removal of upper lobe of lung, and has confidence in its success; he emphasizes the dangers and difficulties caused by adhesions; he believes large incision in the axillary line is most advantageous for operation. Pneumectomy for primary tumor of the lung has never been performed. Schlepfer collected 16 cases of enchondroma in which the chest was opened, with 8 recoveries and 8 deaths. Tillmanns considers that the greatest danger in the removal of these tumors is in the opening of the pleura and mediastinum; not from the pneumothorax but from the infection of the pleura. Terrier advises the free opening of the pleura, regardless of the pneumothorax, for the excision of these tumors. For hernia he favors the reduction without rib resection.

My experiments were made to familiarize myself with the technique and feasibility of the various operations; the manipulation and exposure for observation of certain phenomena were excessive and were not conducive to the recovery of the animals. The following is the report on pneumectomy:

Experiment 2.—Oct. 24, 1897: small brown dog; ether anesthesia; the same antiseptic precautions were used as in experiment 1. Osteoplastic resection of fourth and fifth ribs on right side was made; parietal pleura retained on flap; action of mediastinal septum observed as in experiment 1. Lower lobe of right lung was brought out through and plugged the opening; this relieved all respiratory difficulty; the lobe was transfixed, ligated with heavy silk and two-thirds of the lobe excised; there was no hemorrhage and the lung was returned; a subcutaneous buried suture of catgut entirely closed the wound; time consumed in operation, twenty-one minutes. By a mistake in orders the dog received nothing but water for three days; when the error was discovered he was very weak; he died on October 29, five days after the operation.

Postmortem.—Perfect primary healing of external wound had taken place; there was a slight edema of deep tissues; periosteal flap in good position; on opening the pleural cavity the lung was found to be entirely free from adhesions; the pleural cavity contained no pus or serous fluid; the ligature was in position; pressure necrosis had liberated a small portion of the lung on the side nearest the base; there was no odor from the stump; the remaining one-third of the lobe was normal; there was no pneumonic infiltration; thrombosis had not advanced in the ligated arteries or veins; the bronchi were closed; there was no pericarditis or pleuritis on the opposite side; there was no pathologic cause of death and it was probably due to the error in orders mentioned.

Experiment 3.—Oct. 24, 1897: small black dog; ether anesthesia; an osteoplastic flap of second and third ribs on right side was made; movements of mediastinal septum observed as in previous experiments; the septum was thicker than in the last dog; there was marked cyanosis after opening the pleura; when the hilum of the lung was grasped with forceps so as to prevent the vibration of the septum respirations were rapid,

but the cyanosis and collapse disappeared; the upper lobe was drawn out through the opening and ligated at the hilum en masse with silk ligature; the wound was closed with catgut as before; time consumed in operation, sixteen minutes. The dog left the operating table in good condition but became quite sick the same evening, and continued so until death forty-eight hours after operation.

Postmortem.—Accumulation of pus present between skin and osteoplastic flap; the latter was held fairly well in position by sutures; the pleural cavity was found full of sero purulent fluid; numerous adhesions had formed between the diaphragm and the parietal wall; the lower lobe was partially consolidated with pneumonia; ligature was buried in exudation; pleuritis on left side; pericardium free from inflammation.

Experiment 4.—Nov. 8, 1897; small black dog, weight about thirty-eight pounds. A U-shaped incision with resection of one and one-half inches of the fourth rib on right side was made; osteoplastic flap; the lung was immediately drawn out and three lobes ligated at hilum with catgut without transfixion. The opening in the chest was closed by a deep catgut suture and a continuous silkworm-gut cutaneous suture; time for operation, twelve minutes; November 9 dog in good condition; November 10 dog in good condition, wound looks well;

Fig. 20a. — Shows empyemic cavity after partial contraction has taken place following drainage.

November 11 dog playful but breathing rapidly; November 12 dog in excellent condition; the silkworm gut suture had been bitten out and there was a slight gaping of the flap; air entered and escaped through the skin wound in small quantity; it is believed that this passed in and out of a subcutaneous cavity only and that the pleura was still closed; November 20, dog in good condition, external wound almost closed; no air passing through the opening; the dog became fat and appeared to suffer no discomfort except a slight increase in frequency of respirations; he was killed on March 14, eighteen weeks after the operation.

Postmortem.—A heavy clamp was placed on the trachea to prevent collapse of the lung when the chest was opened; the organs were thus retained in the same position as during life; the external wound had cicatrized and contracted; there was a defect in the bony thoracic wall about one inch in diameter where the rib had been resected; the edges of this defect were covered with shreds of connective tissue. The ends of the rib were smooth and covered with connective tissue. The thyroid gland was much enlarged; the right pleural cavity was small and had in it a few drams of serous fluid; the heart and mediastinal contents were displaced markedly to the right; the delicate mediastinal septum was intact; the pulmonary stump could not be recognized; a mass of connective tissue, firm and glistening, about the size of a hen's egg, occupied its supposed

⁵⁶ Chicago Med. Recorder, 1892, p. 537.

location. Shreds of adhesive bands existed between the diaphragm and chest wall; a few vascular villous shreds projected from the pleural surfaces in various places; the left pleura was smooth and non-adherent; pericardium was normal. The esophagus, larynx, thyroid, trachea, heart, entire left lung, the lower lobe of the right, the anterior thoracic wall and the diaphragm were removed en masse and submitted to Dr. W. A. Evans for pathologic examination, report of which is as follows: The right side of the diaphragm was elevated and attached to the mediastinum and the chest wall. A line drawn through the center of the trachea and continued downward passes through the center of the heart, cleaving its tip exactly in the middle. The entire heart had been drawn to the right, but the most marked displacement was in the swinging of the tip with the base fixed. The sternum was bent to the right, as shown in the diagram (Fig. 20 b.) outlines for which were measured. The bend was most marked at the fourth rib. Two cm. to the right of the sternum and 13 cm. above its tip is an opening 4.5 cm. long, by 2 cm. wide. This opening is covered by a flap in which is a piece of rib 2.5 cm. long; this piece is entirely separated from other bony structure. The space between the

Fig. 20.—Deviation curve in sternum, Experiment 4.

ragged ends of the rib and this piece is scant 3 cm.; all of the surfaces of these pieces show slight nodular periosteal thickening. The soft tissue flap which contains this piece of bone bellows out into a hernial sac, measuring approximately 5 cm. across and 4 cm. in height. Its internal surface is smooth and glistening except for bands of yellow-colored fibrous tissue which run here and there; these blend into the connective tissue of the wall.

Left lung: The lowest lobe is large, fully expanded and has no adhesions to the wall; the middle lobe also no adhesions to the wall; these two lobes are bound together by firm adhesions. Upper lobe; this measures 6x4½x4 cm., is heart shaped, and is covered by firm, thick pleura .8 to .5 cm. in thickness. The pleura has a smooth glistening surface. There are no pleuritic adhesions. The bands of fibrous tissue in this lung run parallel to its surface. The outer layers of the pleura are the densest. The upper lobe of the lung is not attached to the others. The appearance of this lobe is that of a cyst. The bronchial tubes are patulous to the smallest. The lung substance is firmly compressed.

Right lung: The upper lobes of this lung are gone. A

stump containing a small amount of lung is to be seen. (See Figs. 21 and 22). This was excised for microscopic examination. The lower lobe has attachments to the diaphragm which are hard and ligamentous. Its attachments to the pericardium and to the mediastinum are equally as firm. The pleura measures .3 to .5 cm. in thickness, and is firm and dense on its outer surface; is free except at the attachments noted. On incision the lung substance is firmly compressed and the bronchioles are patulous.

Microscopic examination of the stump of the upper lobe shows the following: The end of the bronchus is plugged with fibrous tissue, the bands of which run in every direction. In this mass of tissue are a few bronchial glands. Besides this there is no trace of epithelium. The connective tissue has grown from the mucosa and the inner fibrous coat. The islands of cartilage run in every direction, but the general disposition is to form a triangle. The cartilage plates do not show degeneration phenomena. The vessel wall interior to the inner elastic lamina is thicker than the balance of the wall. The fibers of the wall all run in the same direction. The blood vessels are closed by growths of connective tissue which are mostly inside of the inner elastic lamina. Sections from higher up in the bronchial tree show a small lumen with the mucosa thrown into the usual folds. The epithelium is falling away and much of it is loose in the lumen.

This detailed report is submitted to show the histology of the closure of the vessels and bronchus of the stump; it will be noted that this dog had three lobes in his left lung, and

Fig. 21.—Right lower lobe and stump.

while we had removed three on the right side there was still another left, showing an anomaly of development. Quénou observed that the dog's lung is occasionally divided into as many as six distinct lobes by fissures extending to the hilum.

Experiment 5.—Nov. 8, 1897; large black and white dog; thorax opened on right side, as in previous operations; the mediastinum ruptured and the dog ceased to breathe; after the lungs had collapsed the chest was compressed and the aperture closed with the hand; then the dog began to breathe but with considerable difficulty; on account of rupture of the mediastinum no further attempt was made at operation; the chest was compressed and the muscular flap rapidly closed over the opening with a firm catgut suture and buried catgut subcutaneous suture. November 9, dog in fair condition; November 10, dog sick, breathing rapidly; November 11, dog died.

Postmortem—incision in chest wall adhered per primum; right lung was collapsed; left lung was dilated apparently to normal size; it was slightly emphysematous; there were a number of hemorrhagic patches in the lower lobe; no evidence of hemorrhage or suppuration; cause of death could not be ascertained, but I believe it was due to the rupture of the mediastinum, which impaired his respiration after the closure of the chest.

Experiment 6.—Nov. 25, 1887; large white bull dog; there was the usual preparation and anesthetic; incision was made the same as in previous experiments; the entire right lung

was drawn out through the opening; there was considerable pressure on the hilum to produce this result; a catgut ligature was thrown completely around the hilum; the lung was excised and the stump sutured with catgut in the opening close to the sternal border; there was considerable tension on the stump; time of operation, twenty-minutes. I had hoped by this method to produce an extra-pleural treatment of the stump, but in the dog I could not use the hysterectomy retention needles to hold the stump extra-thoracic; the external wound was closed with buried catgut suture; November 26, dog was very sick; on the morning of the 27th he was found dead.

Postmortem.—Incision firmly agglutinated; the stump of lung was found partially adherent in the incision; there was some blood in the pleural cavity, and a septic pleuritis on both sides; the catgut ligature on the stump had given way.

The difficulty encountered in this case in drawing the stump of the lung forward for extra-pleural treatment should not be experienced in the human, as the longest diameter in the dog is the antero-posterior, while in the human it is the shortest.

Fig. 22.—Posterior view of lobe and stump.

In the cadaver I found it easy to draw the lung out through an opening on the side of the sternum, and believe that in pneumectomy the stump can be treated in this position: it appears from the results in pneumectomy for pulmonary hernia that this treatment of the stump will be the most favorable.

Experiment 7.—Nov. 25, 1897; small black dog; resection of third rib, right side; osteoplastic flap was made; ligation of the hilum of the entire lung above the bifurcation of the large bronchus; stump top sewed. I endeavored to secure a pleuritic flap from the mediastinum and chest wall to cover the stump, but did not succeed; the chest was closed as in previous cases; an aspirating needle was then inserted into the right side and the air in the chest cavity pumped out for the purpose of drawing the mediastinal septum to the side operated, and assisting the expansion of the left lung: this improved the dog's respiration materially; time consumed in operation, thirty minutes; the dog when removed from the table was in poor condition; November 26, dog improving; November 27, in fair condition; November 28, not so well; drowsy; November 29, very sick; November 30, dog died.

Postmortem.—Incision healed per primum; when the pleural cavity was opened air entered with considerable force; there was no bad odor; point of ligation presented a hard nodule of granulation tissue which seemed to be aseptic; the bronchus was closed; left pleural cavity normal; pericardium normal; examination of specimen showed closure of artery and vein with small clot near point of ligature; mucous surface of bronchus granulating; cartilage unchanged; cause of death not ascertained.

Experiment 8.—March 26, 1898; large female dog; an osteoplastic flap of second and third ribs was made; two upper lobes of right lung were ligated at base with chromicized catgut and excised; the stump was covered by suturing the base of the lower lobe over with chromicized catgut to form a cap; this left no abraded surface within the pleura; the dog died on the third day.

Postmortem was made fifteen hours after death; external wound found clean; there was emphysema of chest wall in neighborhood of wound with slight discharge of sero-sanguinous fluid through deep line of sutures; right pleural cavity contained about 500 c.c. of fluid blood with few coagula which were adherent to the stump; the stump was found in good condition, the lower lobe covering about two-thirds of it; the ligatures were in position; the entire parietal and the remaining portion of the visceral pleurae were covered with a thick, hemorrhagic membrane; when this was peeled off the underlying pleura was injected but smooth and glossy; heart normal; pericardium and pleura of opposite side normal. Cause of death, septic pleuritis.

Experiment 9.—April 24; large female dog, 45 pounds; ether anesthesia; an osteoplastic flap of four inches of fifth rib (right) was elevated. This rib I find is the best to resect in dogs, as it permits easy access to the hilum of the lung; on the admission of air respiration ceased; the thin mediastinal septum flapped to and fro and soon became emphysematous from the admission of air between its layers; for two minutes the respiratory efforts continued and then suddenly subsided; the heart continued its regular action; the right lung collapsed, contracted around its hilum and the diaphragm receded; the entire lung was grasped with the fingers and drawn out through the opening; as soon as it plugged the orifice the dog began a rapid gasping respiratory movement which soon became regular and full; the upper and middle lobes were separated from the lower, ligated at the base with chromicized catgut and excised; with three continuous catgut stitches the base of the remaining lobe was sewed over the stump of the excised lobes, forming a cap or covering; the stump was allowed to recede into the chest; there was no hemorrhage; the mediastinal septum was now very emphysematous and bulged greatly to the left side; the left lung could be seen through the delicate septum; a deep row of catgut sutures approximated the muscle wall and pleura and a superficial buried subdermal catgut suture approximated the skin; I used the buried suture as I found it would materially lessen the danger of superficial wound infection; an aspirating needle was then introduced into the fourth interspace and the air aspirated from the right side; this was for the purpose of re-expanding the lower lobe of the right lung and putting the mediastinal septum on tension so as to aid the respiration of the left lung. April 25, the dog had been very quiet and apparently comfortable; she took her food freely this morning; her respirations were, however, rapid; in the evening her respirations were still more rapid but she partook of food; April 26, dog panting and very sick; died at 9 o'clock A.M.

Postmortem.—There was primary adhesion of skin and muscle; when the chest wall was opened there was neither entrance nor exit of air; thirty four ounces of fluid, sero-sanguinolent, flowed out of the wound; on the left side there was a sero-purulent pleurisy with edema of the lung; the lung was greatly compressed; the mediastinal septum bulged far to the left of the median line; the right pleura was covered with a fibrinous exudate about one-eighth of an inch in thickness; it was divided into many compartments by trabeculae of this material extending from the mediastinal septum to the chest wall; lower lobe of right lung collapsed and hidden from view by the fibrinous exudate; the stump was completely covered by the adherent lobe; the death was caused by the large accumulation of fluid shutting off her respiration, there had been no hemorrhage.

Experiment 10.—May 1, 1898; large male dog difficult to anesthetize; when finally overcome was very cyanotic; respired feebly; when the chest was opened respiration ceased; artificial respiration resorted to with no effect; the heart ceased to beat; tracheotomy was then performed and a rubber drainage tube inserted into the trachea; the upper air passages were closed; the lung could be easily made to expand and protrude many inches through the opening, illustrating beautifully the

practical application of Tuffier's method of artificial respiration; it was however too late for restoration.

It was my intention before publishing these experiments to produce a number of herniæ of the lung subcutaneously and later amputate the protruding portions, but time did not permit. This should from clinical experience, be the most favorable method of pneumectomy as Coubey collected fourteen cases of hernia treated by pneumectomy, with twelve recoveries.

I wish to express my appreciation and thanks to Drs. W. A. Evans and George W. Johnson for the assistance rendered me in this work.

SELECTION.

Suture of the Patella.—Macdonald (*Medical News* for July 30) describes a method of treatment of the fracture of the patella, for which he claims uniformly good results, shortened convalescence, freedom from the dangers of sepsis, simplicity, continuance of the encysted silver wire suture, maintaining position of the fragments, and bony union possible in all. He describes his method as follows: "After the usual preparations to secure asepsis have been completed, the limb is fully extended, the surgeon draws the lower fragment of the patella as high as possible, enters the point of the scalpel close to the apex of the bone, and carries it directly inward and upward through the ligamentum patellæ into the synovial sac above the ligamentum mucosum. The scalpel is now withdrawn, leaving a puncture of the joint at its dependent part one-half of an inch in length. This puncture is now covered with sterilized absorbent gauze, and by massage and flexion the joint is practically emptied of effusion through the puncture. Should any difficulty be experienced in removing the effusion, always fluid for several hours after the injury, the metal cannula may be introduced to facilitate the flow. After the removal of the fluid, the fragments can usually be brought in apposition. By a little coaxing, bits of membrane or bursa can be removed from between the fragments, and distinct bone crepitus obtained. An assistant now holds the fragments. . . The point of the needle is introduced into the puncture close to the apex of the patella, carried through its tendon laterally, through the aponeurosis at the side into the tendon of the extensor femoris, keeping close to the patella all the time, and is made to present underneath the skin. A touch with the scalpel permits the point of the needle to be reached, and one loop of silk withdrawn. The needle is then removed, and another loop passed in a similar manner on the opposite side. By means of these two loops of silk the silver wire is drawn into position. The relation of the fragments is now re-examined to determine the absence of tissues between them, and that no tilting exists. When properly adjusted they are steadied by an assistant, while the surgeon, by strong traction on the silver wire, using forceps on each end, buries it in the tissues around the patella and twists it close to the apex. The wire is cut short and buried in the wound. If the process has been carefully followed the fragments will be found in absolute approximation, surrounded and supported by this suture or subcutaneous splint." After dressing the limb in plaster of Paris, "the patient is kept in bed with the foot elevated, for a week, and carefully watched for any reaction. Afterward he is allowed to sit up, and after two weeks go about on crutches. The dressing is removed at the end of six weeks, and a molded posterior splint adjusted. At the end of twelve weeks all dressings are removed and full use of the limb allowed."

PRACTICAL NOTES.

Gangrenous Phlegmons are arrested at once and cured with injections of antidiptheria serum, according to the experience of Dr. E. Monti in thirty-one cases at Pavia. His previous mortality had been from 45 to 80 per cent.—*Semaine Méd.*, July 6.

Sero-diagnosis of Tuberculous Effusions.—Courmont has found that the serous fluid from local tuberculous lesions has a pronounced bactericidal and agglutinating power (17 out of 18 cases), while the fluid from non-tuberculous lesions of the kind has none (6 cases).—*Presse Méd.*, June 11.

Calcium Carbide in Carcinoma.—In the *Kansas Medical Journal* of July 9, Leslie reports two cases of carcinoma of the cervix with calcium carbide (*vide JOURNAL*, July 9, 1898, pp. 63-68), and one case of carcinoma of both cervix and vagina with calcium carbide and Coley's mixture.

To Disinfect the Stools in Contagious Diseases the following mixture is very highly recommended: zinc sulphate, 100 grams; sulphuric acid, 5 to 10 grams; nitrobenzol, 2 centigrams and 15 centigrams indigo. Five grams in a vessel before using will prevent any odor and putrefaction for twenty-four hours.—*Progrès Méd.*, June 25.

Early Diagnosis of Pregnancy.—G. Reusner supplements Noble's two signs (contrast between the enlarged uterus and small neck and sensation of partial fluctuation) by calling attention to the characteristic pulsation of the lateral uterine arteries in the posterior vaginal vault. The pulsation is so strong and distinct with commencing pregnancy that he establishes his diagnosis upon it as early as the fourth week. It resembles the pulse near inflammatory processes.—*St. Petersburg Med. Woch.*, June 25.

Nervous Pseudo-Appendicitis proceeds from the ovary or neuralgia of the twelfth intercostal nerve, in hysterics with exaggerated reactions. The anterior perforating point of this nerve simulates McBurney's point, but the two other points, vertebral and lateral, confirm the hysteric stigmata. It is curable by therapeutic suggestion. A case is described in the *Presse Méd.*, of June 4; a young man who was laparotomized twice and a macroscopically sound appendix removed, returned with the same syndrome of appendicitis for the third time.

Modern Treatment of Burns. Absorbent Compresses.—The *Semaine Méd.* of June 15, calls attention to the following simple and effective treatment of burns, employed by C. Calliano of Turin, with which he has been very successful and which corresponds to the latest theories in regard to burns and intoxications. The part is first cleansed with cold sterile water or a weak antiseptic, using vinegar water for a burn from lime and slightly soapy water in case of corrosion from a mineral acid, after which cold compresses are applied, renewing or moistening with fresh cold water every fifteen minutes. These cold applications relieve the pain at once and abolish it completely in twelve to fifteen hours, after which a compress of sterile gauze or clean cloth is dipped in boricated water at 40 degrees C. and wrung out until only slightly moist but still hot and absorbent, and applied to the burn with an air-tight covering. If there is suppuration this hot compress should be renewed twice a day, cleansing the parts with a stream of boricated water under gentle pressure. If the skin is very red and painful he applies the ointment: lead carbonate and lead oxid aa 2 grams in 15 grams vaselin; or this liniment: limewater, 100 grams; linseed oil, 50 grams, and thymol, 1 gram. As suppuration diminishes, smaller and lighter compresses are applied. The patient must remain in bed during the entire time of treatment to avoid pressure on the wound, and the part must be raised if possible to favor the reflux of venous blood. Simple diuretics and saline purgatives should be given to promote the elimination of the toxins. If there are evidences of auto-intoxication, inject a tenth of a milligram of atropin or a centigram of extract of belladonna, watching the pupils; or else some simple tonic. The urine should be watched, and if the albuminuria increases, showing progressing auto-intoxication, injections of physiologic salt solution are required.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 13, 1898.

HEMOGLOBIN ESTIMATION AND ITS PROGNOSTIC VALUE.

The amount of hemoglobin, estimated upon a percentage basis, is the true index to the richness of the blood. Other ingredients, notably albumin, may aid somewhat; but while the latter may be increased in the blood of fairly healthy subjects with considerable rapidity, hemoglobin increase is comparatively slow, and for that reason is a better indicator, regardless of the time of examination. Another point: we can, as a clinical test, quickly determine hemoglobin percentage, while with the remaining blood ingredients a well-equipped laboratory becomes a necessity for such work. The count of the number of red corpuscles, aside from the specific diseases of the blood itself, can not be regarded as of such value as formerly; for instance, in neurasthenic states, it has lately been demonstrated that counts of six or seven millions per cubic centimeter are not infrequent, yet the physical condition of the patient, together with his hemoglobin, is below par. The determination of hemoglobin is of little value from a prognostic standpoint in the various blood affections proper, but in the simple anemias, from whatever cause, it possesses decided importance. It is the consideration of these latter states that we propose to take up here.

In very few diseases, if any, does anemia occur with such rapidity as in malarial fevers. Nor is this a matter of surprise when we reflect upon the enormous number of spores set free with each paroxysm. Many of these spores penetrate a red corpuscle, and eventually the result is a destruction of their hosts. The

hemoglobin is transferred during the growth of the parasites into minute pigment granules, and these latter are disposed of in various ways; some are deposited in the solid organs, notably the liver and spleen; others become changed into urinary and bile pigments, and as such are for the most part thrown off from the system. The effect of this would become almost a mathematical problem were it not that other factors come into play. Many of the organisms fail to mature extracorporeal parasites; many are destroyed before sporulation; immense numbers are taken up by the leucocytes in the spore stage. Were it not for these facts an attack of malaria would invariably be attended with fatal results after a few paroxysms. With the exhibition of quinin, the majority of cases (the intermittents at any rate) become not cured but convalescent, and the problem now changes to that of improving the nutrition, in other words the abolition of an anemia necessarily present. The usual tonic treatment, iron, quinin, strychnia, Fowler's solution, is instituted, and it becomes necessary to note the effect, if any, of our drugs, especially iron, that the dosage may be regulated and the patient not given more than can be utilized. This can be best done and in a truly scientific manner by determining the hemoglobin percentage. It need not be done oftener than once a week, and even a slight increase during that time will show to the physician that his patient is progressing in the right direction. The estimation is easily and quickly made with the hemometer of Fleischl, but where that instrument is not available another simple and exact method can be substituted. This method of Hammerschlag, as it is called, depends for its working principle on the difference in specific gravity of two fluids, the one heavy and the other light, neither of which will mix with fresh blood. Chloroform and benzol are the ones usually employed. They are thoroughly mixed in sufficient quantities of each to make the united specific gravity 1059, that of the normal blood. A drop of blood is allowed to fall into this mixture, which has been poured into a wide-mouthed test tube. As said before, the blood will not mix with either of the two fluids, and if the specific gravity of the blood is less than that of the mixture the drop will float. Benzol must then be added until the blood remains stationary in the surrounding medium. If the drop sinks, add chloroform until it rises and becomes stationary as before. The specific gravity of the mixture when the drop becomes stationary indicates the specific gravity of the blood under inspection. The specific gravity of the blood bears a definite parallel ratio to the amount of hemoglobin, so that the normal specific gravity, 1059, corresponds to the normal amount of hemoglobin, 100 per-cent. With this as a working basis, a number of tables have been formulated—which can be found in any work on the blood—illustrating the amount of

hemoglobin and the corresponding specific gravity. The most suitable of these tables is that of Schmaltz, in which a specific gravity of 1030 represents 20 per cent. of hemoglobin and a specific gravity of 1045.5, 50 per cent, from which figures alone the ratio can be arrived at approximately. The only contra-indication to the efficacy of this test is a pathologic condition which will increase individual corpuscular weight without increasing the amount of hemoglobin. This occurs in dropsies of all kinds and from whatever cause, and in this class of diseases reliance must be placed on the hemometer. Any of the simple anemias, and the causes producing them are legion, may be readily studied by the above method, and the value of the treatment demonstrated, so that often a favorable prognosis can be given, where without this aid the attendant must be in grave doubt. One other caution must be observed. In syphilis there is always, in the active stage of the disease, more or less anemia. If, to a syphilitic who has not been treated with inunctions or injections, such treatment is instituted, a rapid fall in the percentage of hemoglobin usually takes place, often as high as 10 to 20 per cent. Under active treatment, if not pushed to a great degree, the hemoglobin will return to its original percentage, and under a careful administration of mercurials even increase, so that by estimating the hemoglobin at frequent intervals, and changing the dose to suit the condition of the hemoglobin, we may soon be able to so regulate our dosage as to bring about continuous improvement in our patient. It may be well to add that this peculiar behavior of the hemoglobin to mercurials does not occur except in syphilis, and in such a case is a valuable diagnostic as well as prognostic point.

THE HISTOLOGIC CHANGES PRODUCED BY THE VENOM OF POISONOUS SNAKES AND LIZARDS.

There is quite a remarkable resemblance, in many respects, between the toxic substances produced by microbes, by certain plants, as well as by certain animals. It has been well established that animals can be made immune, not only against microbic toxins, but also against venoms of different origin. Thus, EHRLICH has immunized animals against ricin and abrin, and CALMETTE against the poison of venomous snakes.

There are also certain chemie resemblances between the toxins of various origin, especially in their feeble resistance to heat. There has also been found a certain similarity between the lesions produced in the animals killed by these various poisons. The changes produced in the tissues by the poisons of serpents and lizards have, however, not received very much attention, if any. NOWAK's¹ recent experimental study of the histologic alterations produced by snake

venom and by the poison of lizards is therefore especially interesting.

The effect of these poisons upon the body depends not only upon the toxicity and quantity of the venom, but also upon the manner in which they are introduced. The subcutaneous inoculation does not produce rapid death. On the contrary, if the most minute quantity of the venom of the cobra is inserted into the marginal vein of the rabbit's ear, instantaneous death follows. In this respect the toxic substances from snakes and lizards differ very much from the microbic and certain vegetable toxins. It is well known that the toxins of tetanus and diphtheria require a certain length of time after the introduction before the first symptoms of poisoning leading to death develop. If the poisons of snakes and lizards are injected subcutaneously, the dose may be so arranged that some of the animals die very soon after the injection, others after a few hours up to several days.

NOWAK experimented with guinea-pigs, mice, rabbits and dogs. Macroscopically it was especially noticeable that after death caused by snake or lizard poison, the parenchyma of the liver was friable, yellowish and congested. Similar changes were also present in the kidneys. The microscopic changes were more striking. Their principal seat was the liver, kidneys, and the lungs.

In the liver the change consisted in a typic fatty degeneration of the liver cells, which in some cases resulted in total disintegration of the cell. When the deaths followed very soon after the injection, the protoplasm of the cells was swollen and granular. After a few hours vacuoles and other changes of a degenerative character occurred in the interior of the cells. The quantity of chromatic substance diminished, and the nuclei would lose their affinity for stains. These degenerative changes often lead to total disintegration of the structure of the liver (necrobiosis).

In the kidney there occurred a fatty degeneration of the epithelium, but not to such a degree as in the liver. It was generally confined to the convoluted tubules. Occasionally some fatty changes occurred in the endothelial cells of the glomeruli. Swelling and granular disintegration of the epithelium also took place.

In the lungs, areas of congestion developed, together with desquamation of the epithelial cells of the alveoli and migration of blood corpuscles. At times the number of white corpuscles would be so great that the pneumonia presented a purulent character. The inflammatory changes in the lungs were most marked in the animals that lived for some hours after the injection.

NOWAK calls attention to the similarity of some of these changes to those produced in yellow fever. This fact has already been emphasized by SANARELLI in his work on this disease. NOWAK failed, however,

¹ Annales de l'Institute Pasteur, Juin, 1898.

to find any lesions in the digestive tract as characteristic as those which occur in yellow fever. The inflammatory changes in the lungs are also less marked in yellow fever.

The results of the study of the effects of the poisons upon the nervous system are to be published later.

IMMIGRATION AND INSANITY.

It is now many years since Dr. FOSTER PRATT in a notable study of the United States census statistics showed that the foreign born furnished an altogether undue proportion of the insane and criminals in this country and drew the inference from this fact that, to some extent at least, we were being burdened with more than our reasonable share of European defectives by immigration. Notwithstanding the lapse of time since his publication, something of the same state of affairs still exists, and the opinion has become widespread that it is due, at least in part, to a deliberate unloading of foreign insane and criminals upon our shores. It is well known that this has been done to a certain extent, but whether this goes far to account for the excessive proportion of foreign born in our asylums and prisons is another question. In New York City, the great gateway of immigration, the admissions to the Manhattan State Hospital, which comprises all the public institutions for the insane in that vicinity, the foreign-born admissions for the past ten years are nearly twice as many as those of the native born. This may perhaps be credited to the assumption that, as New York is the chief port of immigration, the defectives have a tendency to be sifted out on the spot, only the more vigorous mentally and physically passing on to the interior or Western States. Allowing this to be partially true, we have, however, still another fact to explain, that is that in the interior or Western States where there is a large proportion of immigrant foreigners in the population they furnish more than half the admissions to the asylums. This is still true in Minnesota and California, and probably also in Wisconsin, and was until quite recent years also the case in large sections of other States such as Illinois. The proportion of immigration to population has decreased, but the disproportion of foreign-born asylum inmates still exists.

When we consider the numbers of these foreign-born insane, and especially when we observe them as they are found in our public institutions, it is impossible to assume that any very large number of these were deliberately unloaded upon us as defectives. A few have certainly been assisted emigrants, but the great mass are unquestionably from the average of their countrymen and not originally more defective than them, so far as any apparent probability and available evidence can show. It would appear therefore that immigration has directly promoted and increased insanity.

Mr F.B. SANBORN, the Massachusetts philanthropist, discusses this subject at some length in a paper read before the Conference of Charities at its last meeting. While he admits that many facts seem to indicate that immigration has furnished us with a class of persons more liable to insanity than are the native born, he calls attention to another fact that, at first sight might seem somewhat contradictory to such a view, namely, the increase of insanity whence the immigrants come. In Ireland, for example, while the population has steadily decreased since 1851 to the amount of nearly 30 per cent., the number of insane has nearly trebled. To come down to more recent times, the same steady decrease of population has continued: the population, which in 1880 was 5,202,648, was in 1896 only 4,560,378. But the total number of insane, which in 1880 was 12,982, had risen in 1896 to 18,966, an increase of nearly 50 per cent. At the same time the Irish immigrants to this country were furnishing an altogether undue proportion of the insane in our hospitals, thus producing the apparent paradox of a country getting rid of its insane by emigration and at the same time and *pari passu* with its decrease of population increasing its home contingent of insanity.

Mr. SANBORN's method of accounting for these facts is not altogether a satisfactory one. He assumes that the emigration, while it carried off the most vigorous and younger class, also included the majority of those at the ages in which mental disease is most likely to occur, while it left in the home country the aged and infirm, those who actually furnish the greater number of mental breakdowns. This last fact would be undoubtedly a valid cause for a proportional increase of insanity in Ireland, for example, but it gives no good excuse for this actual excessive increase with a decreased population. And while we may admit that most cases of insanity occur among the young or middle-aged, it is so because they furnish the bulk of the population, and it does not by any means account for any existing excess of Irish insane in Massachusetts asylums as Mr. SANBORN seems to think. It is a common saying "that it is a poor rule that won't work both ways," but his application of it here appears to have its defects.

Mr. SANBORN's observations would seem to have been more restricted than one would suppose when he says that the Germans and Scandinavians in this country appear to be less liable to insanity than the native born. If he would consult the statistics of the asylums in the States where these nationalities abound and compare them with those of the general population of the United States census he would see the fallacy of such a generalization. It certainly is hardly correct to say that "the German and Scandinavian settlers in the rural States of the northwest seem to show fewer cases of insanity than the native born:" the fact that over 50 per cent. of the insane in a State like Minnesota are of foreign birth and

largely of these races, is sufficient evidence to the contrary.

One cause adduced is possibly effective to a certain extent, but will hardly suffice to account for the whole of the excess of foreign-born insane in this country. The personal habits as to intemperance are unquestionably not so good amongst the foreigners as amongst the native stock, but the difference is more comparative than absolute.

We are forced to fall back on one great general cause for the increase of insanity here and elsewhere, viz., the stress of modern civilization, the greater demands of modern life upon the brain and nervous system. In Europe with its more crystalized social systems, so to speak, large sections of the population, the lower classes especially, have been living under conditions in which the rapid progress of the century has had little effect upon them, and these have furnished a large proportion of the immigrants to this country. Transplanted here and placed on the very advance crest of the nineteenth century, as regards practical life, it is little wonder that many more of them break down, especially when we consider the hardships, disappointments and other trials that many of them must undergo. If this is not alone sufficient to account for the excess of foreign born in our asylums, something may be attributed to the effects of climate as bearing upon habits of drinking, etc., and there are doubtless still other causes efficiently acting of which we may as yet know little or nothing.

The increase of insanity in this country is only an incident to its increase throughout the civilized world. Civilization has altered and redirected the ordinary processes of social evolution and we are here even more than elsewhere in transition, and immigration is one of the active elements in the process.

Mr. SANBORN's conclusion that immigration of itself is not one of the factors in the increase of insanity in the United States is not supported by the facts.

AN ARRAIGNMENT OF THE ARMY MEDICAL DEPARTMENT.

Since all the particulars of the battles near Santiago, Cuba, and the conditions prevailing among the sick and wounded at Siboney and on homeward bound transports have become known to the country, the daily press has been urging the necessity of an investigation to fix the responsibility for these distressing conditions. Editorials have appeared charging the Major-General commanding the expedition with reckless neglect of the welfare of those disabled by the exposures and exhausting labors of the campaign. Other writers have imputed the status to incompetency on the part of the Quartermaster's Department; but by most the Surgeon-General's Office at Washington and the Medical Department at the front have been arraigned as responsible for needless suffering by their inability to realize and meet the necessities

of the occasion. It is claimed, 1, that the expedition sailed from Tampa, Florida, to Santiago, unprovided with the field supplies which would manifestly be required in the event of a battle; 2, that owing to the inefficiency of the medical officers accompanying the expedition even those supplies which had been shipped from Tampa were not available when required; 3, that notwithstanding these deficiencies army medical officers declined the proffered assistance of the American National Red Cross to help remedy them, and lastly, that the shipment of soldiers, wounded and prostrated with fever, on transports which, from their construction and grossly insanitary condition, were unfit for hospital purposes, showed a culpable carelessness on the part of the Medical Department which was aggravated many fold by a failure to provide medical attendance and suitable medical and subsistence supplies for use while en route.

As to the first charge, we learn from medical officers that SHAFTER's army, while at Tampa, was provided with everything necessary for efficient medical and surgical service in the field, and that medicines, dressings, instruments, hospital tents and supplies, were loaded on the transports in quantities more than sufficient to meet the needs of the Santiago campaign. The bulk of the supplies were shipped in connection with the field division hospitals, but accompanying each regiment were regimental supplies largely in excess of the regimental needs, as these supplies were intended, in case of necessity, to supplement the division hospital equipment.

To appreciate the groundlessness of the second charge we must understand some of the conditions pertaining to the disembarkation in Cuba. The troops were immediately marched in the direction of Santiago, and the medical officers serving with regiments, having no means of transporting their medical supplies, had to leave these behind on the transports, and were bereft of all resources except such as were to be found in the orderly and hospital corps pouches of their attendants and in the first-aid packets carried by the soldiers. The partially unloaded transports were ordered to lie to ten or fifteen miles off the landing to be out of the way of the unloading of other transports. Those carrying the equipment of the First Division Hospital and of the Reserve Hospital of the Army joined the naval blockading squadron off Morro Castle and were not permitted to return to land their supplies until five or six days later, the fight at Guasima having taken place meanwhile. The difficulties and delays experienced by medical officers in getting supplies to the front were very great, in view of the fact that no wagon transportation up to this time had been landed. Hospital tents were much needed, but there was no possibility of getting them from the transports. Even much later, when the Hospital Ship *Relief* arrived, it was found impossible

for several days to land her supplies on account of the heavy surf and the want of proper facilities. At the landing-place there was but one lighter, which was constantly in use by the Subsistence Department in getting rations ashore. By the energy and untiring efforts of the officers of the Medical Department their supplies were ultimately landed, although such work is no more their special duty than is the building of an ambulance wagon or the manufacture of a hospital tent.

As to the third charge, the proffer of Red Cross supplies was of no value unless associated with the means of landing and transporting them to the front. What was lacking to the Medical Department at the time was not supplies—for there were supplies on every transport in sight as well as on the *State of Texas*—but the means of getting these supplies to the points where they were required.

In considering the reported condition of the *Coucho* and other transports used in bringing home sick and wounded soldiers it is to be remembered that the Medical Department can do no more than recommend. Its officers may inspect and suggest needful alterations to fit the vessel for its proposed voyage, but commanding officers can overrule their suggestions. Were the outfitting of extemporized hospital transports in the hands of the Medical Department we may be sure that they would be as excellent in their way as the Hospital Ship *Relief*, which was fitted out under medical officers concerned in the despatch of the sick and wounded, but we feel confident that when the facts are learned it will be found that what was considered to be an imperative military necessity occasioned the use of unfit and unprovided vessels, just as it occasioned the landing of the troops and their advance to an engagement with the enemy without any consideration save that of the military purpose in view. Opinions may differ as to whether the accomplishment of the purpose justified the method of its accomplishment.

NOSTRUM MANUFACTURERS AS FRENCH "STATESMEN."

The decadence of the French Republic under the sway of speculative commercialism is most ominously evident in the fact that an opulent nostrum vendor now occupies the position in the recently appointed BRISSON Ministry which was refused a decade and a half ago by the distinguished physiologist, PAUL BERT. Dr. BERT (like Dr. OLIVER WOLLCOTT, one of the medical signers of the Declaration of Independence, who long remained an authority on finance) was a man of admitted skill in political economy. The recently accepted French minister of finance (M. PEYTRAL) owes his reputation chiefly to his success as a manufacturer and promoter of patent medicines.

M. PEYTRAL, after attempting to form a ministry of his own, lately accepted at the hands of BRISSON the

portfolio of finance. He is the first patent medicine "fakir" who has ever held a cabinet position in France. His fortune was made in the manufacture and sale of quack nostrums and the promotion of quack nostrum companies. He pretends to be a representative "business" man of the radical stripe which panders to the bourgeois ideals of supposed thrift (or rather parsimony) of the speculative commercial classes. Until he secured his election as senator, he distinguished himself by puerile poses of the following type: On one occasion, on the eve of a general election, when stumping Marseilles he blatantly pointed out that his rival had come from Paris in a sleeper, whereas he, like a true democratic bourgeois, had traveled in a third-class carriage. The fact, however, was that he also had journeyed in the sleeper and had only quitted this for the third-class car at the last station before Marseilles.

Nostrum-vending is in France even more disreputable than in the English-speaking countries. The *Code Républicain* nominally prohibits the traffic, and only by evasions of the law, such as FLAUBERT pointed out in "Madame Bovary," can it be carried on. The patent medicine vendor is in France, for this reason, a species of confidence operator in a traffic without the pale of the law. The fact that such an individual should be allowed to juggle with French finance is most significant evidence that the "business" quacks (who caused the downfall of France at Sedan) are again in the saddle. Furthermore, it demonstrates that the welfare of the country is again being sacrificed to "business" interests as represented by avaricious contractors. Meanwhile the question naturally arises, what has become of that sturdy element of the French medical profession which so often exercised such a potent influence for good during all three of the French republics, and especially during the first decade of the present one? Great Britain has significantly elevated the deservedly criticised social status of her medical profession by creating LISTER a Peer for services to medical science. France, once foremost in her reverence for science, has of late fallen so far behind in this particular, that the downfall of even the present pretense of republican forms seems foreshadowed by this triumph of a most degrading form of illegal charlatanism over the once politically potent French medical profession.

CORRESPONDENCE.

WAR CORRESPONDENCE.

THE MEDICAL DEPARTMENT OF THE ARMY IN THE CUBAN CAMPAIGN.

BY LIEUT.-COL. NICHOLAS SENN, U.S. VOLS.,
CHIEF OF THE OPERATING STAFF WITH THE ARMY IN THE FIELD.

NEW YORK, Aug. 1, 1898.

DEAR DR. HAMILTON

In an editorial of last week's *Record* Dr. Shradly made an unwarranted attack on General Sternberg. The General tele-

graphed me to reply to it. I have done so, and send you original copy, for which I ask a very early publication in your journal in justice to the General and his Department.

I leave for Porto Rico tomorrow on the steamer *Relief*. On the way down I shall have something to say on the reorganization of the Army. I will send you paper from Ponce. Hoping that you are well, I am, with kindest regards,

Yours sincerely,

N. SENN.

ON BOARD THE HOSPITAL SHIP "RELIEF," July 31, 1898.

In an editorial of the *Medical Record* of July 30, suspicions are thrown out reflecting on the efficiency, foresight and proper management of the Medical Department of the Army during the Cuban Campaign. The remarks made by the editor are based, as he himself asserts, almost exclusively on a correspondence which appeared in a recent issue of the *Sun*. In commenting on this article the editorial states: "If the report is true, and there seems to be no good reason for doubting it, the Army Medical Department appears in a very unenviable light. It is said that there was a total lack of everything necessary for the proper care of the stricken soldiers. Why this was so it is hard to explain, especially in view of the fact that the war department has constantly declared, in declining voluntary assistance from charitable organizations, that it was abundantly able to cope with any possible emergency in the field, and yet this is the result." The correspondent of the *Sun* made bold in saying: "It was evident that the Medical Department of the Army had failed absolutely to send hospital supplies, or by this time they would have been landed. On the one hand it was pitiful. On the other, it was negligence that could have been the result only of incompetence." I am sure if the editor of the *Medical Record* had been better informed he would not have been so willing to lend his ear to a newspaper correspondent whose success nowadays consists largely in tinging facts with more or less imagination and sensationalism. The medical men inside and outside the army have little, if any, influence over the lay press, but the editor of a medical journal of such high standing with the medical profession throughout the entire country as has been willingly accorded the *Medical Record*, should take the necessary pains to investigate more thoroughly the circumstances which dictated the editorial before casting any reflections whatsoever on the chief of the medical department. Dr. George M. Sternberg is no stranger to the medical profession and the American people. He occupies the exalted position of Surgeon-General of the United States Army, not by political preferment or gradual ascent by promotion, but by merit. President Cleveland made a wise selection when he made the appointment. It was a selection that met with the heartiest approval on all sides. General Sternberg knows from long and actual experience what it is to be a soldier in the field. He has been there. He served with distinction during the War of the Rebellion. He has followed the unruly and wily Indians over plains and mountains during many a campaign. He has investigated yellow fever at home and abroad, regardless of his own health and life. Since he has been placed in charge of the Medical Department of the Army he has been tireless in making many much-needed improvements.

The Army Medical School is one of the many fruits of his labors. He has taken special interest and pride in promoting the intellectual and professional advancement of his young army surgeons, assigning them for temporary duty in large cities, where they could enjoy clinical instruction and laboratory work. He has taken a deep and active interest in the organization and usefulness of the Association of Military Surgeons of the United States, and served most acceptably as president. Last year he was honored by the profession by election to the Presidency of the AMERICAN MEDICAL ASSOCIATION. The earnest devotion to his duties made it impossible

for him, to his great regret, to attend the Denver meeting. The name of General Sternberg is often seen on the programs of scientific societies from the Atlantic to the Pacific and from Labrador to the Gulf. He crossed the Atlantic, last summer, to represent his Government at the International Congress, held in Moscow, Russia, and his work there added much to the luster of American medicine. The Surgeon-General, now so unjustly accused of incompetency, not only is accorded a well-deserved place in the front rank of the profession, but his administration shows executive talents which have served him well during the present campaign. He has shown good judgment in the selection of his advisers. Colonels Alden, Greenleaf and Smart, are all men of large experience and admirable executive abilities, as all can testify who have been brought in contact with them. The charge of incompetency and ignorance certainly lacks foundation in the case of General Sternberg and his administration. Now, as to facts. The correspondent of the *Sun* who furnished all the material for the editorial referred to goes on to say: "The wounded were carried back from the fighting line on stretchers, and laid on the ground to wait until the surgeons could reach them. Many were soon beyond the need of surgical treatment. There were four divisions of the army, and each division was supposed to have its hospital; but as a matter of fact there was but one, the division hospital of the Fifth Army Corps, under Major Wood. There were five surgeons, a hospital steward, and

Brigadier-General George M. Sternberg, Surgeon-General of the Army.

twenty assistants, to care for the wounded—several hundred. They had a number of operating tables, a small supply of medicines, but few bandages, and no food for sick or wounded men. It was comparatively easy to get supplies from the *State of Texas* ashore to the hospital here (Siboney), but there was no transportation to the front." In the opinion of the editor of the *Medical Record* and the correspondent of the *Sun* the Red Cross Association's work was the only redeeming feature of the whole campaign, to judge from the language of the latter: "God knows what we should have done here without the help of the Red Cross—your ship, your surgeons, and your nurses! and there is no other help for us at the front. Our wounded up there must have food, bandages, anything you can let us have in the line of hospital supplies." The editorial in the *Medical Record* brings matters to a focus in the closing extract: "It is right and proper that the Surgeon-General should resent any interference with his prerogative, but he should not directly invite it by making possible such

a condition of affairs as here described." This inference is entirely unwarranted by facts as they existed during and after the battle of Santiago.

The correspondent and editorial do not even mention the steamer *Olivette* we found July 7 anchored close to the shore before Siboney. This steamer, in command of Major Appel, U. S. A., was used as a hospital ship. This ship was in place and ready to receive the wounded during the battle. The steamer, at the time mentioned, had on board 300 wounded, who received the best surgical attention and nursing. The next day the steamer left for the United States, the medical staff being reinforced by the addition of Acting Assistant-Surgeon Brown of Chicago from the *Relief*. General Sternberg at an early date recognized the importance of hospital ships during this war. The *Olivette* was chartered for this special purpose, was well equipped and reached the seat of war in time. The hospital ship *Relief*, formerly the *John Englis*, under the supervision of its commander, Major Torrey, was transformed into an ideal floating hospital in less than six weeks and reached Siboney July 7, a day before the *Olivette* left for its home port. Do these things show either negligence or ignorance? Do they not rather demonstrate foresight and an earnest endeavor to better care for the sick and wounded in a way creditable to our country and the chief of the Medical Department? This question can safely be left for the wounded to answer. The Surgeon-General accepted the legitimate services of the Red Cross Association and had reason to expect aid from this source, should pressing emergencies present themselves. The medical officers, the wounded and the sick have every reason to be grateful to Miss Clara Barton, for what she did in furnishing ice, delicacies and medical supplies. The *State of Texas* did excellent work in aiding the Medical Department, but that is no reason why those connected with the Red Cross Association should claim all the credit and undertake to criticise a department of the government which has done all it possibly could in anticipating the requirements of a sudden emergency. It is a source of great regret that there should be any friction whatever between the Medical Department and the friends and supporters of the Red Cross Association. It must be clear to every unprejudiced mind that the treatment of the sick and wounded must remain under the direct care, control and management of the Medical Department, and that the function of Red Cross is rather auxiliary to it than as an independent organization if the greatest amount of good is to be realized from it. The hospital ship *Relief* brought an immense amount of medical supplies, delicacies, cots, pillows and blankets. When we arrived at Siboney we knew our presence was much needed, and looked in vain for some one to inform us where and how to land. The precipitous and rocky nature of the shore and the great depth of the ocean made it unfavorable to secure anchorage for several days. A single lighter attended to the demands of numerous transport ships. I am sure no one could blame the Medical Department for the unavoidable delay in unloading the supplies. The little steam launches did what could be done in bringing to the shore what was most needed. Major Torrey worked night and day in supplying the requisitions made by the surgeons in the field and hospitals. There was no red tape here, all they had to do was to inform him what was wanted and it was delivered as soon as it could be brought to the shore. The lack of proper transportation facilities from the landing to the front can not be charged to the Medical Department. It took more than a week of the hardest kind of work to land all of the supplies. and, considering the limited facilities available, it is and always must be regarded as a source of satisfaction that it was made possible at all. The *Relief* brought 1000 cots and an ample supply of blankets, which reached the hospitals with as little delay as possible.

Lieut. Crabbs of the 8th Cavalry, showed a creditable degree of ingenuity, energy and often of courage in landing the supplies. The complaint that the sick and wounded lacked medicines and dressing materials is true only to a certain extent. Some of the medicines were exhausted, owing to the unexpected enormous demand, but they were supplied as quickly as could be done under the existing circumstances. The writer had the privilege to operate in all of the hospitals and was always able to find the essential antiseptics and dressing materials required in military practice, and this was at a time when the supplies were at the lowest. There was no lack at any time of stimulants and anesthetics. There is no use in denying the fact that immediately after the battle the tentage and blanket supply were inadequate, but these defects were corrected promptly. War always has had its hardships and discomforts; it can not be prosecuted in parlor care and clubhouses. Or soldiers expected deprivations and unavoidable discomforts, but on the whole they were subjected to less actual suffering than they had reason to look for. To the credit of the medical officers it must be said they shared the inevitable hardships with the soldiers. They lived on the same food, drank the same water and made the moist ground their beds. The writer will always cherish the memory of the hardships incident to a campaign in a foreign country, a tropical climate and among a strange people. The Cuban campaign was planned and executed so quickly that some omissions and defects had to be expected. It is a source of gratification to know that the complaints made against the medical department have come from newspaper correspondents and camp followers more than from the soldiers themselves. Among the thousands of sick and wounded with whom I have been brought in contact during the Cuban campaign I have seldom heard a complaint; on the contrary, I have heard nothing but words of praise for the hard working, self-sacrificing medical officers and the department they represent in the field.

Ice-Water Enteroclysis in Typhoid Fever.

TOLEDO, OHIO, Aug. 1, 1898.

To the Editor:—After having had favorable results with ice-water flushings of the bowels in the lowering of high temperatures in typhoid fever, I have wondered that greater stress is not laid upon the use of the measure by those who write upon the treatment of that disease.

The cases are few in number in which I have had the opportunity to test the practice, and it may be that these few cases were such as would have done well under the Brand method, the wet pack, or any other plan of refrigeration; indeed, such is doubtless true.

For several reasons though, my practice, limited as it is, leads me to look upon ice-water enteroclysis as superior to any other method of lowering the temperature which I have seen used.

In the first place, fever patients need much more water than they in their semiconscious condition are likely to ask for, or than they will drink when it is offered them, and it is always the fact that there is less water passed into the bedpan than was forced into the bowel.

I place this reason first because I believe it is important that these patients take into the system more water than they are accustomed to drink even in health, and sterilized water to which has been added common salt, thrown into the bowels, is a rational way of meeting a vital requirement.

I do not know how high the water ascends in the bowels, but that it does hasten the removal of poisonous material from the bowels there can be no doubt. I believe, too, that subsequent injections ascend higher than the first ones did, the bowels becoming more accustomed to the water. The formation of intestinal gases is diminished by the cleansing of the bowel, and the soft rubber rectal tube frequently reaches an

accumulation of gas, thereby relieving a troublesome tympanitis as well.

Patients are not frightened or fatigued by the operation, but, on the contrary, so far as can be told by the expression of countenance, and by their general condition, are made more comfortable by it.

When the temperature is low, nervous manifestations are usually quiet, but whether this quiet is caused by a direct influence upon the nervous system or whether the nervousness is secondary to high temperature is a matter for individual speculation, but I believe that the heat centers are quite as apt to be influenced for good by the abstraction of heat from the interior of the abdominal cavity as they are by radiation from the surface of the body.

Enteroclysis is much easier to administer than is any kind of bath, and hence is much surer of being properly attended to. The technic is simple.

A long, soft, rubber catheter is slipped upon the ordinary hard tip, a napkin is tightly wound around the tip until a hard ball is formed which is to be pressed against the anus to prevent the ejection of the enema. The catheter is oiled with petrolatum and as soon as the tip has entered the anus the water is permitted to flow and, by rotating the catheter to and fro with the fingers, it floats upward as the water expands the intestine, and used in this way it does not double upon itself, or cause rectal irritation. The instrument is retained in the bowel for twenty minutes, the nurse maintaining pressure upon the anus during the time, and when the water is allowed to come away it is found to have the temperature of the bowel. The fountain should not be higher than a foot above the patient's body.

The patient weighs 150 pounds and his temperature is 105 degrees, $150 \times 105 = 15,750$. Water, four pounds, at 32 degrees, is introduced. The heat which this abstracts from the body is the difference between 32 degrees and 105 degrees $\times 4 = 292$. The original heat units, $15,750 - 292 = 15,458$; $15,458 \div 150 = 103$; and it has been my experience that the axillary temperature a half hour after the enema could be predicted with almost the above mathematic exactness.

J. S. TRACY, M. D.

306 W. Woodruff Ave.

Flannel Underclothing for Soldiers.

CLINTON, ILL., Aug. 6, 1898.

To the Editor:—There has been a good deal said of late about our soldiers in Cuba wearing abdominal bandages, "cholera pads" to protect them from diseases of hot climates. I do not think much of the pad. I think it would be better protection and more sensible to furnish each man with two pairs of flannel drawers, which would protect the soldier's legs as well as his abdomen. The extra pair could be kept dry and clean ready for a change and would make but little additional weight or bulk to carry.

I agree with Surgeon-General Sternberg that the field is no place for female nurses. They are all right in the local hospitals, but the battle-field and on the march is not their place. It was so during the Civil War and it can not be otherwise in the war with Spain.

JOHN WRIGHT, M.D.

Proposed New Designation.

SAN DIEGO, CAL., Aug. 3, 1898.

To the Editor:—With the advent of a new century the time is propitious for dropping such meaningless appellations as "Old School," "Regular," "Allopath," etc. Why not, henceforth adopt the eminently distinctive and appropriate title, "New School of Scientific Medicine," suggested by Surgeon-General Sternberg in his recent address at Denver?

Faithfully yours,

C. M. FENN, M.D.

ASSOCIATION NEWS.

Comment on Association Proceedings.—In connection with the proceedings of the Association of American Medical Colleges, published in this number, it is well to note a resolution adopted by the AMERICAN MEDICAL ASSOCIATION, which is far-reaching in its effects. The resolution was introduced by Dr. Dudley S. Reynolds of Louisville, the president of the Judicial Council of the College Association; it was referred to the business committee, approved by it, and adopted with no opposition. (For resolution *vide* JOURNAL, July 9, p. 83.) This resolution practically makes a new qualification for membership for every County society in affiliation with the AMERICAN MEDICAL ASSOCIATION, since one cannot enjoy the full privileges of membership unless he is eligible to serving his society as a delegate to the AMERICAN MEDICAL ASSOCIATION, and it is a question whether the Association was competent to adopt it in this form, for it is, in effect, an amendment to the constitution. It is not to call attention to this structural weakness but rather to its dynamics. That a resolution of this character could be presented to two successive general sessions of the AMERICAN MEDICAL ASSOCIATION and not be adversely discussed, even by the benevolent advocate of the poor young man who must struggle to enter the profession at all, and therefore should receive a training making many of his class monuments of ignorance and incompetency, seems almost too wonderful to be true. Whatever may have been the private opinion of many who kept silent, public sentiment is in favor of a fitting educational period for the intending physician. We congratulate the College Association on their having the stamp of approval set upon their own standard, and, which is a source of greater gratulation, the decision of condemnation upon any course less thorough than their own.—*Bulletin Am. Acad. Med.*, August, 1898.

Politics in the American Medical Association.—If one may judge by the tone of a recent editorial in the *Ohio Medical Journal*, in spite of the fact that Columbus is the meeting-place of the AMERICAN MEDICAL ASSOCIATION for next year, there is not an abiding peace in the minds of the profession of that State. There is a good deal of truth in the statement of the *Ohio Medical Journal* that "the political part of the convention continues to be managed by medical politicians; these gentlemen constitute a sect apart, come chiefly from St. Louis and Louisville, and come with everything cut and dried," but granting it, there are many who will not give the matter the prominence which it evidently receives at the hands of our contemporary. Most of the members attend the sessions of the AMERICAN MEDICAL ASSOCIATION for other reasons and with other purposes than to engage in political bickerings, and are only too glad that there are some who are willing to do this work for them. If they think they are running the show, let them think so as long as the performance continues; they get but an empty honor, forgotten before the next session, and have a great deal of labor for their pains. While they are doing this work the rest of us can meet and chat with friends, attend Sections, visit places of interest and enjoy ourselves. The men who are so unfortunate as to be elected to office will earn all they get from the honor, scores of times over, before next June.—*Atlantic Med. Weekly*, August 6.

Resolutions Submitted to the American Medical Association at the Denver Meeting, June 8, 1898, by W. H. Sanders, M.D., Health Officer of Alabama. (*Vide* JOURNAL, No. 2, Vol. xxxi, pp. 85 and 95, July 19, 1898). Finally referred to the Business Committee:

WHEREAS, The protection of the public health is one of the duties and functions of all well-organized and progressive governments; therefore, be it

Resolved, 1. That it is the sense of this body that a public health system correct in principle, complete in detail and appli-

cable alike to every part of the country, should at the earliest time possible be created and put into vigorous operation.

2. That in order for such a system to be constitutional, coherent and permanent, it should logically conform to the genius and plan of our concentric systems of government, that is to say, its roots should be deeply planted among the people, the recognized source of governmental power under our constitution, and its branches should reach up through, and be sustained by, every political division of our State governments to one central and resourceful power, the Nation.

3. That to lay the foundations for such a system the States should formulate their policies of public health with sufficient uniformity as to render them susceptible of being united into one symmetric and harmonious whole, and to lead up to, and terminate in, one central and co-operative head, viz., the general government acting through a bureau of public health.

4. That while the officials for actively conducting a public health system should be of local origin and authority, and therefore directly and proximately responsible to the people, the States and the Nation should co-operate with the local authorities in furnishing the expert skill and financial aid necessary for suppressing dangerous contagious and epidemic diseases when they appear in any given locality, and for preventing their spread from one part of a State to another part of the same State, or from one State to another State.

5. That the principles herein announced should apply to the theory and practice of quarantine, which, although an important part and function of a public health system, is not the only one of its numerous and beneficent powers. To divorce the exercise of quarantine power from a public health system, and to confer it upon a separate organization which derives its existence and vitality from the general government, and not from the people of the States, would be to emasculate and ultimately to destroy said system, as well as to overthrow one of the most sacred and valued principles upon which our government is founded.

6. That an earnest appeal is hereby made to the Congress of the United States to recognize the principles herein proclaimed as constitutional and unassailable, and as in thorough accord with the generic truths out of which our political fabric has been evolved.

SOCIETY NEWS.

American Public Health Association.—The Twenty-sixth Annual Meeting of this Association will be held at Ottawa, Ontario, Sept. 27-30, 1898. The executive committee has selected the following topics for consideration:

- "The Pollution of Water Supplies."
- "The Disposal of Garbage and Refuse."
- "Animal Diseases and Animal Food."
- "Car Sanitation."
- "Steamship and Steamboat Sanitation."
- "The Etiology of Yellow Fever."
- "The Relation of Forestry to Public Health."
- "Demography and Statistics in their Sanitary Relations."
- "The Cause and Prevention of Infectious Diseases."
- "Public Health Legislation."
- "The Cause and Prevention of Infant Mortality."
- "Transportation of Diseased Tissues by Mail."
- "The Period During which each Contagious Disease is Transmissible and the Length of Time for which each Patient is Dangerous to the Community."
- "Sanitation, with Special Reference to Drainage, Plumbing and Ventilation of Public and Private Buildings."
- "Report upon some Method of International Arrangement for Protection Against the Transmission of Infectious Diseases."
- "Disinfectants."
- "To Examine into the Existing Sanitary Municipal Organizations of the Countries Belonging to the Association, with a View to Report upon those most Successful in Practical Results."
- "The Duties and Responsibilities of the Healthy Man for his own and others' Health."

Upon all the above subjects special committees have been appointed. Papers will be received upon other sanitary and hygienic subjects.

Southern Indiana Medical Society.—The Annual Meeting will be held at Indian Springs, Ind., Aug. 11 and 12, 1898. (George Knapp, M.D., President, Vincennes, Ind.; T. A. Hays, M.D., Secretary, Burns City, Ind.)

PUBLIC HEALTH.

The Sale and Importation of Saccharin and other similar sweetening substances; dulcin, crystallin, etc., have been forbidden in Austria to all but druggists.

"To see Ourselves as Others see us" has been recently applied in the campaign against alcoholism in Germany. Drunken men are followed home from the saloon and photographs taken of their most disgusting and humiliating poses. The photographs are then presented to the subject when sober, with a warning circular.

Health in Michigan.—The report of the State Board of Health for July cites rheumatism, diarrhea, neuralgia, bronchitis and tonsillitis as the five most prevalent diseases of the month. Compared with the preceding month, dysentery, cholera infantum, cholera morbus, diarrhea, inflammation of the bowels and intermittent fever increased, while influenza, pleuritis and measles decreased in area of prevalence. The Board celebrated its quarter centenary August 9, 10 and 11.

Health in Indiana.—The diseases most prevalent throughout the State for July were typhoid fever, diarrhea, intermittent fever, dysentery and cholera morbus. As compared with June, the diseases which increased in prevalence were mostly water-borne diseases, as typhoid, dysentery, cholera infantum, inflammation of the bowels, diarrhea, intermittent fever and puerperal fever; those showing decrease were "house diseases," i. e., such as are due to bad ventilation, e. g., rheumatism, tonsillitis, bronchitis, whooping-cough, etc.

Bubonic Plague on the Island of Formosa.—The Japanese physicians have been making a careful study of the small epidemic of fifty cases, which is summarized in the *Arch. Klin. de Bordeaux* for June. There were 22 deaths: 4 natives, 4 Japanese soldiers and 42 laborers. Constipation was the rule in three-fourths of the cases; the rest had a yellow diarrhea, but there was no albuminuria nor pneumonic expectoration. The blood contained, besides the bacilli, an exaggerated number of white corpuscles. The prognosis depended upon the condition of the heart, which grew weaker and weaker until final collapse about the fourth day. Camphor and quinin proved absolutely ineffectual. An abrasion of the skin was only discovered in six cases. The liver was hypertrophied in six, and the spleen in nearly every case, but these conditions were ascribed to preceding malaria or beriberi. If the patient survived five days recovery was probable.

Prophylaxis of Gonorrhea.—The recent German Dermatologic Congress concluded its long discussion of gonorrhea with the recommendation that in view of the present unsatisfactory results of treatment it is important to educate the public, especially young men, to realize the dangers and far-reaching results of gonorrheal infection. As prophylactic measures, instillations of silver nitrate or of 20 per cent. solution of protargol and glycerin immediately after coitus, were advised, and especially the use of a condom. Neisser and others confirmed their previous endorsement of protargol as the most effective and least irritating of the silver salts, but for chronic cases the stronger argentamin is desirable. For women Neisser prefers ichthyol and urethral pencils. The importance of commencing treatment as soon as possible after infection was strongly urged. Neisser and others consider matrimony allowable when repeated examination fails to show any gonococci, but a few take the ground that marriage is impossible as long as any urethritis persists.

Osteopathy in Indiana.—An interesting contest between the Indiana State Board of Health and the osteopathic school of physicians has just come to a close in Lafayette (July 30). Some weeks ago Dr. Gott of Crawfordsville, a member of the Board, called the Board's attention to the fact that the osteo-

paths practicing in the State had not taken out either State or county license, as required by the new State medical law. The osteopaths stated that they were not engaged in the practice of medicine and were not required, therefore, to take out license. They furthermore urged that even should they apply for license, the State Board would refuse it. The State Board is made up of representatives of the allopathic, homeopathic and eclectic schools, and it has been its policy to refuse the application of all who are not regular graduates of one of the three schools. When the osteopaths defied the Board, it was decided to make a test case, so Dr. Woodruff, who had recently come from the Institute of Osteopathy at Kirksville, Mo., and located at Lafayette, was arrested for not taking out a license before engaging in the practice of medicine. The trial of the case was bitterly contested, both sides being represented by the best counsel in the State. The court found Dr. Woodruff guilty as charged, and fined him \$40. Woodruff has taken an appeal to the supreme court, and will endeavor to have the law declared unconstitutional. The State Board will cause the arrest of all other osteopaths practicing in Indiana.—*Globe-Democrat*, St. Louis.

The New York Quarantine Station has imposed upon it a stupendous task, which it barely meets, owing to the arrival of the various army hospital vessels from southern latitudes where yellow fever is a constant menace. The *N. Y. Tribune* gives a cut of the disinfecting boat, the *James W. Wadsworth*, on duty alongside a newly arrived steamer. Dr. Alvah H. Doty, the health officer of the port, has long since discarded alleged disinfections by sulphur and substituted steam in lieu thereof, a method first suggested by Dr. Edward R. Squibb of Brooklyn, N. Y. At first there were many obstacles to be overcome, but finally the present apparatus, in use for two years, fulfilled all expectations. The *Harvard*, the largest vessel disinfected, underwent the process in two days' time, and thus saved to the Government hundreds of dollars a day in the speedy release to her duties. Under the old process two or perhaps three weeks would have been consumed. The vessel in question, it must be remembered, according to Dr. Doty's account, had about 500 men aboard, every one of whom had clothing and bundles by no means above suspicion. The steam used had a temperature of 230 degrees F. or over, but formaldehyde gas is also resorted to in instances where injury by steam to fabrics, such as silk, laces, leather goods, etc., would result. Other devices for the prevention of communication by the development of incubative cases are used.

NECROLOGY.

CHARLES S. WARD, M.D., Yale, 1863, formerly of New York City, died July 31, aged 55 years. He was a member of many associations, among which were the University Club, the St. Nicholas Society and the Society of Colonial Wars. Having retired from a very active practice several years ago, he took up his residence in Bridgeport, Conn., where he died. He was noted for his quiet charities and benefactions.

CHARLES MORRIS FISCHER, M.D., Oakland, Cal., professor of histology of Cooper Medical College, San Francisco, Cal., died July 29. Dr. Fisher was taken sick about five weeks ago and his illness rapidly developed into typhoid fever. He was a native of Pennsylvania, 32 years of age, went to the Coast several years ago and soon after his arrival was made assistant city superintendent of schools. During his college days he became deeply interested in the study of histology and about four years ago, when the chair of assistant professor of histology became vacant, was chosen to fill the vacancy. Later, he was made professor, with the retirement of the former incumbent of the chair.

EDWARD LEWIS STURTEVANT, M.D., Harvard, 1866, died at

his home in Framingham, Mass., July 30. He was born in Boston, Mass., Jan. 23, 1842, was graduated from Bowdoin College in 1863, served as a captain in the Twenty-fourth Maine Volunteers during the latter year, but left the army for a medical career. As an expert in scientific agriculture he was connected with the United States government for many years and in 1881 took charge of the New York State Experimental Station at Geneva, where he remained for six years. Besides his many contributions to agricultural papers he edited *The Scientific Farmer*, 1876-79; *The North American Ayrshire Register*, and, with Joseph N. Sturtevant, published "The Dairy Cow," a monograph on the Ayrshire breed of cattle.

GEORGE C. HUBBARD, M.D., New York University Medical College, 1857, died August 3, at his home in Tottenville, Staten Island, N. Y., of which town he had been a resident for forty years. On January 1 he was appointed assistant sanitary superintendent of the health board, which placed him in charge of the Staten Island branch. After serving in the Civil War as assistant surgeon and subsequently as surgeon of the One Hundred and Sixty-fifth Volunteer Infantry, he returned to Tottenville and resumed practice, succeeding his father. He was for many years physician at the Mount Loretto Mission of the Immaculate Virgin, where there are from 800 to 1000 boys. In 1890 he was appointed a member of the Richmond County Police Board and continued in that place until 1896. From 1893 until 1895 he was president of the County Board of Excise. He also served as health officer of the town of Westfield and of Tottenville during its village history.

JOSEPH M. COCKRILL, M.D., Baltimore, Md., July 23, aged 50 years.—Joseph B. F. Fuller, M.D., Norwich, Conn., July 31, aged 87 years.—Theodore H. E. Gruel, M.D., Philadelphia, July 31, aged 52 years.—Joseph M. Klecfus, M. D., Detroit, Mich., July 30, aged 40 years.—E. T. Long, M.D., Bethlehem, Ky., July 21, aged 78 years.—Henry Mullen, M.D., Philadelphia, July 31, aged 64 years.—Thomas Murray, M.D., Beaver, Pa., July 31, aged 89 years.—Ed. B. Oatman, M.D., O'Fallon, Ill., July 30, aged 51 years.—Jacob S. Shimer, M.D., Philadelphia, July 27, aged 62 years.—T. R. Odell, M.D., Spokane, Wash., July 1, aged 82 years.—W. D. Boker, M. D., Astoria, Ore., July 1, aged 53 years.

DEATHS ABROAD.—Dr. Carlo Giacomini, professor of anatomy in the University of Turin, aged 57 years.—Dr. Victor Michaux, surgeon to the Civil Hospitals of Metz, aged 70 years.—Dr. C. Dufay, formerly senator for the Loir et Cher, president of the Medical Association of that Department.—Dr. Ernest Cadéze, medical superintendent of the Lunatic Asylum of Liège and a very distinguished entomologist, aged 71 years.

BOOK NOTICES.

Exiled for Lese Majesté. By J. T. WHITAKER, M.D. Cloth. Cincinnati: Curtis & Jennings, 1898.

A little love story endeavors to hide the true purpose—a series of remarks on literature, art, medicine, astronomy and kindred topics, chiefly in the form of conversation between the three leading characters. Their talks and readings are blended with apt quotations, in the handling of which the distinguished author is an acknowledged master. In his remarks on medicine he has woven many neat sentences that will soon be "familiar quotations." "Medicine must be a fascinating study." "The science of it is. Practice is very different." Again: "The redeeming element in practice is the diagnosis; that is the knowledge of the nature of disease." "I should think it would be the cure." "The people judge a physician by the results of his treatment; but physicians judge each other by the correctness of the diagnosis." "What is the objection to the practice of medicine? It must be one of the highest of arts." "So it is; but as an art it is subject to

debasement, and still more so as a trade. The charlatan is of all creatures the vilest. He is the vampire who sucks the blood of the sick; but the people at large do not know it, and they rarely draw the lines. Regular, irregular or defective, they are all doctors." A physician when pressed for a more favorable prognosis is made to say: "Only the charlatan is always certain." Again: "The physician does not pretend to still the storm; he is simply a pilot, who is satisfied to steer the ship through." "But the pilot sinks with his ship," said the librarian. "The physician's reputation goes down, too," replied the doctor, "and often under the decrees of Heaven, over which he has no control." In speaking of the death of a famous emperor, "He had the fatal consultation of the whole faculty." "If there was as much difference of opinion among medical men with regard to the treatment of disease as among bankers concerning the remedy for financial distress, or among scholars as to the interpretation of a difficult passage, the human race would long since have become extinct. But it is good to know that the medical men have their day, if it is only the last day." "But why don't you teach your patients?" "They want to be cured only; they don't want to be taught." "There is more in the blood than we have dreamed of in our therapy."

Atlas of Syphilis and Venereal Diseases, including a Brief Treatise on the Pathology and Treatment. By Prof. Dr. FRANZ MRACEK of Vienna. Authorized translation from the German. Edited by L. BOLTON BANGS, M.D. Pp. 122. Philadelphia: W. B. Sanders. 1898. (From W. T. Keener, Chicago Agent.) Price \$3.50 net.

The clinical material figured in this book is drawn from the service of Dr. Mracek in the Rudolfo Hospital in Vienna; this will be recalled as the hospital made famous by the lamented Billroth. The plates are lifelike and the material comprising the clinical cases quoted is such as to be very instructive. The careful study of the clinical statements and the examination of the plates will amply repay students and practitioners. The glance through the book is almost like actual attendance upon a famous clinic.

Handbook of Materia Medica for Trained Nurses, including the sections on Therapeutics and Toxicology and a Glossary of terms with dose and use of each drug. By JOHN E. GROFF, Ph.G. Pp. 235. Philadelphia: P. Blakiston's Son & Company, 1898. Price \$1.25 net.

The text of this book presents an abridgment of the subject of materia medica and there are questions appended to each chapter. There is an extensive glossary at the end. The work is intended primarily for students and trained nurses, but any medical man can read it with advantage.

Lectures on Tumors. By JOHN B. HAMILTON, M.D., LL.D., etc. Third Edition. 21 Illustrations. Pp. 143. Philadelphia: P. Blakiston's Son & Company. 1898. Price \$1.25 net.

The last edition of this book was published in 1892, and many changes have taken place in the pathology of tumors, which have been mentioned in this volume, not included in its predecessors. The work has been greatly enlarged; almost rewritten.

The illustrations are mostly original, and the classification followed by the author is the last revision of the nomenclature of the Royal College of Physicians. Of considerable interest is the latest theory of the origin of the dermoid cyst by parthenogenesis, and Ruffer's description of his microbe of carcinoma.

The publisher has apparently spared no pains to secure the typographic excellence of the volume.

The Retrospect of Medicine. Edited by JAS. BRAITHWAITE, M.D., London. Assisted by E. F. TREVELYAN, M.D., B. Sc., M.R.C.P. Cloth. Pp. 436. Vol. 117, January June, 1898. London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd.

This half-yearly volume contains the usual retrospective view of discoveries and improvements in the medical sciences during the period covered. The abstracts from articles appear-

ing in medical journals during the half year are arranged under the heads of "General Medicine and Therapeutics," "Diseases of the Nervous System," "Diseases of the Organs of Circulation," "Diseases of the Organs of Respiration," "Diseases of the Organs of Digestion," "Diseases of the Urinary Organs," "General Surgery and Therapeutics," "Nervous System," "Alimentary Canal," "Affections of the Eye and Ear," "Affections of the Skin," and "Obstetrics and Gynecology." The volume is up to its usual standard of excellence.

The Mental Affections of Children; Idiocy, Imbecility and Insanity. By WILLIAM W. IRELAND, M.D. Pp. 442. London: J. & A. Churchill. Edinburgh: Jas. Thin, 1898. Price, \$4.00, net.

Those who read the author's former book on idiocy and imbecility will recognize a great deal that was in that work, but the present work is more elaborate and treats more exhaustively of the condition.

The pages on the development of the brain in childhood, the pathology of genotoxic and paralytic idiocy, sclerotic and syphilitic idiocy and that on insanity of children are new and not contained in the former.

This work deals with statistic causes of idiocy, and takes up at length the question of hereditary and, indeed, idiocy in all the phases.

The author strenuously objects, as do most philanthropists of the present day, to the practice of placing idiots in wards with the insane, and takes up the question of their careful treatment and final restoration to the body politic. The neglect of the States and failure to provide sufficient accommodations for this unfortunate class, is as a rule, owing to the absence of accurate knowledge as the exact amount of benefit that can be secured for them. Such books as this have therefore an important mission in popular education.

A Manual of Bacteriology, Clinical and Applied, with an appendix on bacterial remedies, etc. By RICHARD T. HEWLETT, D.D., M.R.C.P., D.P.H. Pp. 439. Philadelphia: P. Blakiston's Son & Company, 1898.

In this manual the author has endeavored to give some account of those portions of bacteriology which are of special interest in clinical medicine and hygiene. The preparation of tissue, methods of culture, description of pathogenic organisms and their detection, the examination of water, etc., have therefore been given at some length. The direction for staining and preparation of cultures, in the examination of air, water, blood, etc., are fully discussed.

This book will be very useful for those whose laboratory facilities are limited.

Thirty-Seventh Annual Report of the Cincinnati Hospital. Paper. Pp. 178. Illustrated. Cincinnati: Commercial Gazette, 1898.

This report covers the year ending Dec. 31, 1897, contains a description of the Cincinnati Hospital, reports of the various officials and the branch hospital with detailed tabulations concerning various cases of typhoid fever, acute rheumatism, pneumonia, hernia, etc., occurring in the hospital.

Twelfth Annual Report of the State Board of Health of Ohio. Cloth. Pp. 508. Illustrated. Norwalk, Ohio: Laning Printing Co., 1898.

Besides the usual matter pertaining to sanitary questions, this report contains a number of papers of interest. Among others we note "A Report on the Treatment of Diphtheria with Antitoxin," "What Can be Done for the Prevention of Consumption," "Evil Results of Present Educational Methods," "Present Position of Formaldehyde as a Disinfectant," and "Tuberculin Test for Tuberculosis in Milk Cows."

Handbook for the Hospital Corps of the U. S. Army and State Military Forces. By CHARLES SMART, Deputy Surgeon-General, U. S. A. Approved by the Surgeon-General of the Army. Second Revised Edition. 12mo. pp. 358, illustrated, blue muslin, \$2.25 net. New York: William Wood and Company.

This is the third revision of the well-known handbook of

Colonel Smart and deserves a place in the library of every military surgeon. As its author is an accomplished chemist, it is natural to expect that the chapters on sanitary care of camp, etc., would be of the highest order.

The appearance of the book is timely and it will be found of great use to the medical corps in the field.

A Compend of Diseases of the Skin. By J. F. SCHAMBERG, M.D. Pp. 137. Philadelphia: P. Blakiston's Son & Company. 1898.

There are ninety-nine illustrations in this volume. The illustrations are excellent and the text up-to-date. The student will find this as useful as any of its much derided but nevertheless very necessary class.

NEW INSTRUMENTS.

A COMBINED EUSTACHIAN INFLATOR AND EAR AND NOSE DOUCHE.

BY WILL WALTER, M.D.
CHICAGO, ILL.

The use of the Politzer air-bag in Eustachian inflation is decidedly clumsy and not entirely satisfactory for several reasons. It is necessary to hold the nasal tip in one nostril and to exclude the other with one hand, that the other may be free from pressure upon the air-containing bag; while, too, the shape of the bag is awkward and the whole instrument unduly large and hence difficult to carry when emergency requires. In addition there is great variability in the volume and force of the air through difficulties of compression and through the kinking, softening or hardening of the rubber tubing. These apparent defects led me to try a small bulb with a nasal tip directly attached for this purpose. Subsequently, in view of the usual demands for intranasal and postnasal treatment in connection with inflation, and frequently with this douching of the external auditory meatus, I thought to substitute for the simple nasal tip a reflex tip of special shape, hoping thus to meet all the demands in one instrument.

The instrument shown in the cut thus consists of an ovoid rubber bulb, specially shaped and sized to be easily compressed by the hand, attached to a hard rubber reflex tip, to the return flow portion of which is applied a piece of small tubing. The latter may be in length according to the desire of the patient. The tip is adapted as well as possible to meet the needs of both nose and ear, fitting the average external orifices as well as may be done by one instrument. The instrument should prove of value for Eustachian inflation, as it may easily be held to the nostril and compressed by one hand, while the other hand holds the opposite nostril, the exit tube being closed.

As an ear douche, its simplicity, convenience and cleanliness of application would commend it for hot douching of the external meatus.

As a nasal douche it may be used for douching the nares in cases where there is pathologic or post-operative occlusion and it is desired to cleanse the parts, and this it will do much more readily than the spray. By entirely compressing the exit tube a nasal douche, easily regulated in force and area of

application by variation in pressure, may be attained. Few physicians do not, at times, need to restore the normal pressure to the middle ear, and this is most advantageous when early employed. The compactness of this instrument, together with its varied uses, would seem to commend it for routine use in practice.

103 State Street.

MISCELLANY.

Globulicidal Properties of the Tapeworm.—Schauman and Tallqvist report that the bothriocephalus latus, whether derived from an anemic or non-anemic person, contains a true blood toxin.—*Deutsche Med. Woch.*, May 19.

The Fifth International Congress for the Study of Potable and Mineral Waters, Climatology and Geology, will be held at Liège, Belgium, from September 25 to October 3. Secretary, Dr. Jorisienne, Boulevard de la Sauvenière, 130, Liège.

Prof. William H. Welch has resigned as dean of the Johns Hopkins Medical School. Dr. Welch does not sever his connection with that institution, for he will retain his position as professor of pathology.

Consolidation of Colleges.—The consolidation of the Atlanta Medical College and the Southern Medical College under the name of the Atlanta College of Physicians and Surgeons, is announced. This will be the only regular medical college in Atlanta.

From a Study of the Agglutinating Power of Cholera Vibrios, Ransom and Kitashima have demonstrated that the agglutinating power of a cholera culture can be modified at will without appreciably affecting its virulence or other characteristics, by varying the specific cholera serum.—*Deutsche Med. Woch.*, May 12.

Inflammable Stomach Gases.—Dr. Drouet relates that he was recently examining the throat of his three-year-old child with a tongue-depressor, by the light of a candle, when the gases rising from the stomach caught fire and burned for a moment with a bluish flame, slightly singeing the doctor's mustache and the child's lips.—*Jour. de Méd. de Paris*, July 3.

Pus in the Pelvis.—Johnson (*Am. Jour. of Obstet.*, July) believes that the majority of bad pelvic pus cases, etc., could be more quickly evacuated through the vagina than through the abdomen, and at the same time done more easily, completely and safely. He reports twelve cases tending to emphasize this conviction.

Bile Not Secreted by the Liver.—Barbera concludes from numerous tests on dogs with biliary fistulas that the bile is not a secretion of the liver; the functions of the liver do not include the secretion of bile, which is merely an excretion of the liver cells, its production depending upon the work of the cells.—*Munch. Med. Woch.*, May 24.

In 104 Total Extirpations of the Uterus for carcinoma at the Landau Clinic, 27 per cent. have shown no signs of recurrence during the five years since; 32 per cent. have relapsed. Neither youth nor extreme age seems to be absolute counter-indications for an operation. He has had three fistulas persist. He recommends completing the operation at one sitting and removing both ovaries every time.—*Munch. Med. Woch.*, May 17.

Congenital Pelvic Kidney.—Cragin (*Am. Jour. of Obstet.*, July) reviews the literature on this subject and adds one case to the few already reported, obstruction of the parturient canal resulting. His conclusions are: Pelvic kidneys may cause dystocia; induction of premature labor is indicated as a rule; in rare cases, where the pelvic kidney is in a condition of hydronephrosis, vaginal nephrectomy may be advisable. In the writer's case vaginal nephrectomy was performed.

Official Privileges Extended to Women Physicians.—A recent decree places women occupying official medical positions in Russia on the same footing as men, with the exception of promotions, wearing uniforms and decorations. They do not lose their right to a pension if they marry, and their orphan children inherit it. The decree only refers to a limited number who completed their medical course under certain circumstances. Woman has long been legally on an equality with man in Russia.

Pride Before a Fall.—Pedagogic father is trying to show off his supposed precocious boy before company.—“My son, who would you rather be, Shakespeare or Dewey?” Little son meditates awhile and says, “I’d rather be Dewey.” “What, my son; and why?” “Cause he ain’t dead.”—*New York Weekly*.

The Importance of the Role of the Phagocytes is much enhanced by the new discoveries in regard to their action in tetanus intoxication. They not only destroy the bacteria, but owing to their property of absorbing all the solid particles they encounter, they absorb and render harmless the tetanus toxin if it is combined with a solid substance, such as brain matter. These facts show that the leucocyte is capable of destroying a microbe even when it is secreting a virulent toxin.

The Absorption of Calomel by Leucocytes after injections into the tissues proceeds very rapidly where the circulating current is rapid and where they reach it before its transformation into mercuric chlorid. In the subcutaneous and muscular tissue the leucocytes merely surround the calomel without absorbing it or carrying it away. The transformation, therefore, only occurs at the point injected, and is promoted by the fluids of the organism. Vaseline holds the calomel in suspension longest and is absorbed by the subcutaneous connective tissue in one minute.—G. Piccardi, *Derm. Cbl.*, April.

Stricture of Small Intestine.—In the *Phila. Med. Jour.* of July 9, Matas presents an illustrative case of multiple stricture of probable tubercular origin, within thirteen inches of the jejunum. He performed enterectomy by Maunsell’s method, not applicable in all cases, *e. g.*, contraindicated in case of very thick or inflamed mesentery, where he considers Czerny-Lembert or other simple suture methods preferable. The case is of interest from the almost insurmountable difficulties of diagnosis before operation, the high position of the lesions, the period of evolution of the stenotic process, twenty years, and the apparent cure.

Porro Operation vs. Total Hysterectomy.—Boldt writes on this subject in the *American Journal of Obstetrics* for July. He believes total hysterectomy should be performed in preference to supravaginal hysterectomy with extraperitoneal treatment of the pedicle; never be performed unless absolute indications are present, and the child being dead *in utero*, the uterus should be removed *in toto* unopened. He considers the advantages of total hysterectomy over the Porro operation as less danger of infection, no danger from secondary hemorrhage, less danger from intestinal obstruction, shorter convalescence and less danger of ventral hernia.

Sharp Practice.—Lady V. (At office of fashionable Harley Street consultant.) “I have called, Doctor, to ask if there is any cure for sleep-walking of several years standing. Lately it has become worse.”

Dr. Hy Pryce: “It can be cured, madam. Take this prescription and have it filled at Cold, Steele & Co’s.”

Lady V.—“Cold Steele & Co.? why, that is not a drug store; it is a hardware firm.”

Dr. Hy Pryce.—“Yes, madam. The prescription calls for a paper of tacks. Dose, 2 tablespoonsfuls scattered about the floor before retiring.”—*Vanity Fair*.

This was for the purpose of puncturing her tire.

The Central Nervous System in Acute Anemia shows the effect of

the intoxication from an insufficient supply of oxygen, as the red corpuscles decrease in number. In a case Scagliosi has recently studied, uterine hemorrhages persisting thirty-four days in an otherwise healthy woman in the eighth month of pregnancy, the evidences of the lack of nutrition were very pronounced. In the brain cells the Nissl cell-corpuscles had crumbled into fine granules, and the accessory nucleus had a hole in or near the center, close to the wall. The atrophy and chromatolysis of the ganglia cells of the spinal cord were accompanied by diminished staining power on the part of the crumbled Nissl corpuscles. He adds that it would be impossible for cells thus degenerated to take up the oxygen, even if it could then be supplied them.—*Deutsche Med. Woch.*, May 19.

La Societe d’Autopsie is an offshoot of the Paris School and Laboratory of Anthropology and it is difficult to overestimate the importance of its work in the study of the organs of men who were prominent and widely known in science, art, literature, politics, etc. Gambetta is the subject of the latest report issued by the society. It contains his “psychologic biography; the brain and the function, with the authentic history of his disease and death,” and throws a remarkable light on the organic substratum of Gambetta’s superiority as an orator and extemporaneous speaker, as it shows that the foot or “cape” of the third left frontal convolution, the verbal motor par excellence, was double in him.—*Bull. de l’Acad. de Med.* June 21

Unorganized Charity.—The medical profession is about the only calling in life that is not, or need not be, dependent upon organization to enable it to give safely, wisely and quickly. The needy are always with us, and all that is needed is a plenty of this world’s goods and a kindly temperament, for, as the poet says:

So many gods, so many creeds,
So many paths that twist and wind,
While just the art of being kind
Leaves all the other arts behind.

Orthoform in the Organism.—It has been demonstrated in Leyden’s clinic that besides its local anesthetic effect, orthoform is absorbed in the stomach and eliminated (not pure) through the kidneys, relieving pain in the urinary passages in acute gonorrhea and cystitis; dose 1 to 1.5 grams a day, preferably in a solution. In the urine it responds to the same tests as the amido-phenol group, most marked with chromic acid, and also produces the ring characteristic of pyramidon. The amido-phenol leaves the organism paired with sulphuric acid, shown by the much increased amount of “ether sulphates.” Orthoform also has the property of preventing the putrefaction of albumin. After the ingestion of orthoform the urine can stand for days without ammoniac putrefaction.—*Deutsche Med. Woch.*, June 30.

A Walver of Privilege.—The first appellate division of the supreme court of New York holds, in the personal injury case of *Rauh vs. The Deutscher Verein*, that the plaintiff, having submitted evidence, whether it be the testimony of the plaintiff herself or of another witness present, of the transaction between the patient and physician, waived the privilege of excluding the physician’s testimony; and the truth of what happened, and what was ascertained by the physician in his examination and the treatment of the patient, can be testified to by the physician. A different rule, it thinks, would work the greatest injustice, and would expose the defendant to danger on account of the fact that the rule would prevent him from examining into the truth of the plaintiff’s statements.

A Colossal Roentgen Plant.—Professor Trowbridge of Harvard University has completed a vastly powerful apparatus for experiments in electric force, his principal object being to test further the penetrating power of the X-ray. The apparatus consists of a series of 120 Franklin plates, or leyden jars, supplied with power by a storage-battery containing 10,000 plant

cells. The voltage necessary for experiments is 2,500,000. It is reported that he has already made experiments which prove that with an apparatus as powerful as this the X-rays can be made to penetrate not only human flesh but bones and tendons, thus probably making possible still more remarkable attainments in surgery by their aid.

Enforced Higher Education.—The Association of American Medical Colleges, which is an organization first brought into actual existence by Dr. Eugene F. Cordell of Baltimore, has done a noble work in raising the standard of medical education in the United States, and in gaining for our country the respect and admiration of foreign medical schools and physicians. There are some schools in this country, however, which did not join this association, and which still "cut rates," so to speak, and by shortened courses and various tricks carefully omitted from mention in the annual catalogues and announcements, help to lower the standard of medical education in this country. In order to force these schools into the association and make them the equals of all the good schools, the AMERICAN MEDICAL ASSOCIATION has passed very practical resolutions declining to register as delegate or permanent member any physician who shall hold the position of teacher or professor in these low-grade schools, or who shall be a graduate of such schools. If the AMERICAN MEDICAL ASSOCIATION has the grit to stick to this resolution, and will not be overpowered by the political members of the association, the effects of this rule will have a very salutary effect on the poorer schools.—*Maryland Med. Jour.*, July 23.

Removal of Health Officers at Pleasure.—Physicians appointed as health officers for cities, towns and counties "may be removed at any time by the local boards appointing them," under section 2060 of the Kentucky Statutes. This, the court of appeals of that State construes, in *Riffe vs. Finsby*, to be equivalent to power of removal at pleasure or discretion, though the general rule is that a person appointed or elected to an office, the term of which is prescribed, cannot be removed therefrom, by even the appointing power, except upon trial of charges preferred, and of which he has notice. Nor does it consider that the case is altered by a city ordinance fixing the term of office of the health officer, whether valid or not, though it is suggested the ordinance would be beyond the power of the city to pass, the State statute not fixing any term of the office in question, and it being plainly the policy of the legislature that there should be no term of such office, and the incumbent should be, for manifest reasons, removed at the pleasure of the board of health.

Fibroma of the Nasopharynx.—Woodson (*Laryngoscope* for August) believes that few, if any, cases of nasopharyngeal fibromata occur which cannot be successfully extirpated or destroyed without endangering the patient's life. He says: "The mode of operation has little or no influence in preventing symptoms, because the tendency to recurrence is marked during the period of active development; the arrest of development follows adolescence, but absorption frequently takes place, when total extirpation of the growth is rarely followed by recurrence." He considers hemorrhage a great danger in operating, and that the galvanocautery loop, while exceedingly rapid, fails to absolutely prevent serious hemorrhage. On the other hand, the cold-wire *deraseur* is bloodless, painless and easily manipulated, and the instrument *par excellence*. He does not advise the injection of escharotics, on account of the density of the growth requiring considerable time for the separation of the slough and also causing offensive odor.

The Sequel of a Druggist's Revenge.—The London *Lancet* cites a case before a provincial police court, in which a small boy who had been swinging on the supports to the blinds of a druggist's shop, after capture had been liberally dosed with an infusion of quassia. The druggist was fined properly, says the

Lancet, on the following grounds: the next mode of punishment might not be so harmless as quassia and the executioner might be less instructed in therapeutics. Again, an element in this way might be imported into the punishment of children which should never be tolerated, to wit, the element of nervous terror. "We know and the druggist knows," says our contemporary, "that the solution of quassia was as harmless as, say, many sorts of table beer, but the boy did not know it. He might easily believe that his disagreeable sensations were the prelude to impending death from poisoning, and a fond mother might possibly support the view, with the result that much more pain, and of a different sort, would be caused than was intended." Although there is a dash of casuistry mingled with the heavy humor of the bar we hope that the controversy is now at an end, especially since the deterrent factors of stronger blinds or increasing weight of years may be the safeguards.

Hemorrhagic Internal Pachymeningitis.—In the *American Journal of Medical Sciences* for August, Herter writes on this affection as it occurs in children, believing that the lesion is sufficiently frequent to deserve more attention than it has hitherto received. From his own observations he says: "I do not feel certain that there is any symptom or combination of symptoms which we meet in hemorrhagic internal pachymeningitis which we may not occasionally encounter in the course of a severe acute infection without the presence of any cerebral lesion whatever. At the same time hemorrhagic pachymeningitis is a lesion which we should think of as a possibility whenever we meet with unilateral rigidity and convulsions, with deepening stupor, in a cachectic or rachitic child under one year of age. In the absence of the signs of pneumonia and tuberculosis, I think this diagnosis gains distinctly in probability." Another aspect to which he calls attention is the probability of slight traumatism to the head, causing rupture of vessels in a highly vascular membrane, giving these cases thus a medico-legal importance.

Puerperal Sepsis.—Mundé, in his presidential address recently delivered before the Am. Gyn. Society (*Am. Jour. of Obstet.*, July), said: "Unquestionably in the large majority of cases of puerperal sepsis in private practice the infection comes from the fingers or instruments of the physician or the nurse; and this statement applies not only to the poorer classes, but to a certain extent to those in better circumstances. It has been frequently stated that the women in well-conducted lying-in asylums are far safer from puerperal infection than those who are attended in their own houses, even though they be brown-stone fronts. This is not as it should be. It is not only the hands and instruments which may introduce infection, but also the clothing of the attendants, which may have been in contact with some infectious case and which have not been thoroughly cleansed and disinfected. . . . Naturally the denuded endometrium, the more or less bruised and lacerated cervix, vagina and perineum are by far more susceptible to the entrance of septic germs than the more or less intact sexual organs during pregnancy. Retention of portions or clots or membranes does not necessarily mean their decomposition and a septic infection. In some cases he believes the septic germs, "wherever they came from and however they got there, were sucked into the gaping vagina during change of position of the patient, say from the back to the side, or *vice versa*, or after a fecal evacuation, when the relations between the pelvic viscera and intra-abdominal pressure changed so that the gaping vulva was placed in a favorable condition for the entrance of air by suction."

Value of Gratuitous Medical Treatment can not be Recovered.—That he had been put to great expense for medicines and doctor's bills, was averred by the plaintiff in a personal injury case as one of the elements of damage which he had sustained for which he should be allowed to recover compensation. But

the evidence was that he had been taken to a hospital and treated there, without incurring any liability for the medicine and medical attendance. Could the value of such medical treatment, what would have been charged for it, if charged for, be made the foundation of such a claim as that stated? The supreme court of Missouri holds, in the recent case of *Morris vs. the Grand Avenue Railway Company*, that it could not. The proof of the value of the gratuity exerted in one's behalf in relief of an injury inflicted, it maintains, is in no sense the proof of the expense to which one had been put, or the liability incurred, in the relief from that injury, and that there is no warrant in law or logic for holding to the view that the proof of the one state of facts justifies the finding of the existence of the other, or that proof of one raises the presumption of the existence of the other. To authorize a recovery on part of the injured plaintiff, there must have been an actual loss to him, or a liability that same may or will occur, and when loss has not or can not occur, by reason of the action of others, gratuitously exercised in behalf of the party injured, or when no legal liability has arisen, by reason of restrictions of law against the intervening third party performing the needful services, it quotes cases to show, no action can be maintained. Nor does it consider that it is any answer to the denial of the defendant that the plaintiff has been put to expense for medical treatment to say that "the defendant in an action for personal injuries caused by his or its negligence ought not to profit by the generosity, charity, or indulgence extended to plaintiff by a third party."

Pregnancy Following Ventrofixation.—A. Laphthorn Smith of Montreal (*Am. Jour. of Obstet.*, July) reports that in his 111 cases pregnancy has taken place in six, one or both ovaries and tubes having been left in four and both ovaries and tubes in the other two. He cites replies to 100 inquiries addressed in May, 1898, to the leading physicians in America as to whether they knew of any cases of pregnancy following ventrofixation. Of seventy-three replies received, thirty-two knew of no such cases, and the experience of forty-one aggregated 148 cases. From the evidence he concludes: 1. That as far as curing retrodisplacement, either retroflexion or retroversion or anteversion with retroversion is concerned, ventrofixation with two buried silk stitches through the peritoneum and fascia gives the most reliable results. Failures are unknown when the operation is performed in this way. 2. Ventrofixation should be reserved for cases in which abdominal section is necessary for other reasons. . . . When it is expected that pregnancy may follow some other operation should be chosen; because, 3, when the uterus is firmly attached to the abdominal wall and pregnancy follows, trouble of some kind, either pain, miscarriage, or difficult labor requiring obstetric operations, takes place in about 30 per cent. of the cases. . . . 4. When *suspensio uteri* was performed, that is, the uterus attached to the peritoneum of the abdominal wall, a few relapses occurred. . . . 5. A third method, it is claimed by some, namely, the intra-abdominal shortening of the round ligaments, is preferable to either fixation, ventrofixation or *suspensio uteri*. After the menopause, it may be added, none of the objections urged are tenable.

Cholelithiasis of Typhoidal Causation (*vide JOURNAL*, June 11, p. 1415).—The London *Lancet*, July 9, refers to the work done by Dr. H. W. Cushing, at the Johns Hopkins Hospital, in elucidating the intercurrent of gall-bladder trouble with the presence of the bacillus of typhoid fever in the human economy. Dr. Cushing, *in primis*, has confirmed the view that the gall-bladder, like Peyer's patches, is a site of election for the typhoid bacilli. In 1891 Blachstein noticed their constant occurrence in the gall-bladder of rabbits after experimental inoculation. Later, Professor Welch discovered that they persisted in this situation; in one animal they were found 128 days after inoculation, when they had disappeared from every other organ. Acute cholecystitis may appear in the late stage

of typhoid fever, but there is a group of cases in which it appears some months after the attack and always in association with cholelithiasis. The connection between typhoid fever and cholelithiasis was first pointed out in 1889 by Bernheim and has been confirmed by several writers. In professor Halsted's clinique in Johns Hopkins Hospital, ten out of thirty-one cases of cholecystitis with cholelithiasis, which were operated on, gave a history of typhoid fever, the interval varying from a few months to twenty years. Such a long interval by no means negatives the connection, for the bacillus has been found in a case of cholecystitis as late as fourteen years after an attack of typhoid fever. Similarly, abscesses of bone may follow typhoid after long intervals: in a case recorded by Buschke the interval was forty-six years and yet the bacillus was cultivated from the pus. These cases well illustrate that the germs of disease may remain latent in the body for an indefinite period, a doctrine which is only beginning to be appreciated and which has far-reaching possibilities. Dr. Cushing reports a remarkable case of cholecystitis and cholelithiasis in which cholecystotomy was performed and the typhoid bacillus found in the gall bladder, although there was no history of previous typhoid fever. The blood serum gave the typhoid reaction. The wide-spread recurrence of the typhoid bacillus has only been lately recognized. In 1892 Guarnieri first described an infection of the biliary passages, liver and spleen without intestinal lesions.

Foreign Bodies in the Ear and Nose.—In the *Medical Record* of June 11, Barret urges more careful knowledge on the part of the general practitioner as to the removal of foreign bodies from the ear and nose. He advocates the use of as few instruments as possible—a head mirror, one serrated and one rat-toothed forceps, foreign body forceps, a flexible tube, a "nest" each of aural and nasal specula, and a cotton carrier, being the essential instruments. In case of the nose he has "the mother or nurse take her seat upon a straight-backed, steady chair, with her back to the table or stand, on which the lamp is placed in such a position that the light shines over her right shoulder. Then she should take the child on her lap, clasp its limbs between her knees, and with her right arm thrown across its body secure its arms, while with the left hand on its forehead she holds its head firmly and steadily against her right shoulder. The operator then places himself in front of the patient, seating himself upon a straight chair or stool (never use a rocking chair), and with the thumb of the left hand slightly tips up the end of the nose, while the right hand so adjusts the head mirror as to throw a flood of reflected light into the nostrils. Having located the foreign body, proceed as quickly as possible to remove it before the child becomes frightened or the nervous strain upon the mother becomes too great. No force should be used under any circumstances, lest the delicate parts be seriously injured. If possible, grasp the offending body with a pair of forceps, and by gentle traction withdraw it; or very often, as in the case appended, the flexible probe may be bent in the form of a hook of suitable size and slipped past the obstruction, then turned, and the foreign body rolled along the floor of the nasal fossa, until it either drops out or can be grasped by the fingers. Sometimes it is necessary to use a nasal speculum and dilate the nares considerably before we can locate a foreign body or effect its removal. The procedure is much the same in case of the ears, but usually more difficult and great care must be taken to avoid laceration of the walls of the auditory canal. The child's head should be turned so as to bring the affected ear toward the operator, and held as directed above. A syringe and warm water may be tried, taking care, however, not to use too much force and thereby rupture the drumhead, and also to dry the ear thoroughly afterward with a little absorbent cotton on a cotton carrier. In examining the ear the lobule is grasped between the index and middle fingers and gentle traction made upward and backward,

while the thumb and index finger insinuate the speculum into the orifice with a slight rolling motion. The speculum most generally used resembles the one for the nose, except it is longer and pointed."

The Mortality of the Medical Profession.—The report of Dr. Tatham, the medical officer of the local government board, on the mortality of occupations during the three years 1890-92 has recently been issued by the Registrar-General as a supplement to the report of the Registrar-General for the ten years 1881-90. The report is one which demands careful examination, and we hope to refer to it at greater length on a future occasion. We will now only observe that Dr. Tatham reports that the number of members of the medical profession recorded in the last census of England and Wales was 18,936, an increase of 25 per cent. as compared with less than 3 per cent., which had been the rate of increase in the previous ten years. The comparative mortality figure for medical men is 966, as against 821 for lawyers, 533 for the clergy and 953 for occupied males in the aggregate. The mortality among them is higher than that of lawyers at all ages up to the 55th year. Dr. Tatham, however, has some grains of comfort, for he finds that in the three years with which he deals the diminution in the death rate of ages under 45 noticed by Dr. Ogle has continued, while at ages from 45 to 65 there has been a decrease from the high rate of 1880-82, although the mortality still remains somewhat higher than in 1871. At ages above 65 there has been a further increase in the mortality. As on the whole the increase has been at ages above 55, Dr. Tatham suggests that it may be partly due to the influenza epidemic, which was at its height in 1891, and is known to have been especially fatal to persons beyond the prime of life. It is a remarkable fact that the most frequent of all causes of death, not only in the medical but also in the cleric and legal professions, are diseases of the heart. Pulmonary tuberculosis and diseases of the respiratory system, which, in most other occupations, stand higher than any others in the scale of mortality, occupy much less important places, the mortality from bronchitis in the medical profession being not more than one-seventh of that to which the general male population is subject. The causes of death to which medical men appear to be especially liable are gout, diabetes, urinary disease and suicide. It appears, indeed, that the tendency to the commission of suicide has notably increased among medical men. The number of deaths attributed to diseases of the liver, of the urinary organs and to alcoholism has decreased. On the whole, if we omit the increase in suicide, it would appear that the death rate from causes which may be classed as preventable shows a decided tendency to decline in the medical profession.—*British Medical Journal*.

The United States Army Field-Hospital System.—The hospital-corps of an army is divided into two detachments, one of them being for service in the field hospitals, the other for manning the litters and ambulances for the removal of the wounded from the field. The laying out of the field hospital proceeds on four lines, separated by intervals that must be determined by the nature of the battlefield. The first line of hospital service is coincidental with the line of battle, and includes regimental surgeons, orderlies and company bearers. On the second line are the first dressing stations, at the nearest point beyond range of the enemy's fire. Here ambulance surgeons attend the wounded, and ambulances and litter-bearers of the hospital corps convey the wounded to the third line. This is called the ambulance station. Reception, operating and dressing tents are erected, where the wounded can be attended until they can be removed to the division hospital at the base of supplies. None of the hospital corps serves in the line of battle. The wounded are conveyed to the first dressing stations by privates from the ranks. The army regulations provide

that four privates from each company shall be designated as company bearers. They are taught how to handle wounded men and in first aid, in addition to their regular duties as armed combatants. They fight in the line until their services are required to attend the wounded, whom they convey to the first dressing places. There the injured are turned over to the hospital corps, and the company bearers return to their places. They are under the direction of their own officers and have nothing to do with the dressing of wounds. Their only care is to convey the wounded beyond the reach of the enemy's fire. At the first dressing stations, where the wounded receive their first attention, aside from such hasty bandaging as the regimental surgeons may be able to provide, there is a completely equipped field hospital in miniature. In the United States Army the main medical stores are carried in army wagons, but as these can not keep up with the line of battle, it is proposed that pack mules be employed to carry such supplies to these dressing stations. A medical case or pannier, so built as to fit the back of a mule, contains all the materials required, a variety of antiseptics, medicines for the relief of pain, bandages, splints, plasters and operating instruments. A cook accompanies each of the divisions, carrying a case of portable cooking utensils. As soon as this detachment reaches its station tents are put up, the medical cases are opened and their contents placed in readiness for use; an operating table is improvised by placing two of the folding panniers together, so that they will afford a place on which to lay the wounded while the surgeon is working over them, while the cook sets up his tent and makes ready to prepare light nourishment.

Not Liable for Leaving Fragment of Needle in Perineum.—A surgeon and physician, who holds himself out as such to the public, and accepts employment as such for pay, does so under obligations which are imposed upon him by law. He takes upon himself the obligation when he accepts such employment that he will exercise fair, reasonable and ordinary skill in the conduct and discharge of that employment. The highest possible skill is not to be expected of him, but it is expected, and the law demands of a person holding himself out as a professional man, that he shall have such knowledge, such skill, and shall exercise such care as are ordinarily exercised by men in his profession in good standing in the community in which he resides. This is the rule which the court of common pleas of Hamilton county, Ohio, took for its guidance, in the case of Eislein against Palmer, where it held, June, 1898, that, according to the evidence offered by both parties, it was manifest that the surgeon sued for malpractice had exercised all reasonable care and skill, and there was no negligence on his part. In performing an operation to remove some cicatricial tissue from the perineum, the needle used in passing the suture was broken, and the surgeon could not find the fragment by touch or sight, and speedily closed the operation, on account of the patient having become very weak under the influence of the anesthetic. Two days before the date set for the patient to receive final instructions and leave the hospital, the surgeon's horse ran away, throwing him out of his buggy upon his head, so that he was not able for months thereafter, either mentally or physically, to attend to any business. Other doctors took the case from that point, and about a year later performed an operation, finding the fragment of needle embedded in cicatricial tissue which had formed all about it, in the perineum, apparently just where it was left when it was originally broken off. Such being the case, the court holds that a verdict in favor of the surgeon was not against the weight of the evidence or the law. It also particularly holds that the surgeon was under no obligation to tell his patient or her husband, while she was his patient, that a needle had been broken and part left in her body, but that it was his duty to tell her when he should discharge her as his patient from his care as such surgeon or physician; because to tell her would only be to endanger the success of the operation. He did not have to anticipate dangerous and unavoidable accidents, continues the court, but he had a right to expect that he would be able to attend his patient until she got well.

The Cause of Death From Electric Shocks.—In these days in which electricity is coming more and more into everyday use; in which after an accident the first thought is frequently, if not usually, as to who is responsible and from whom may financial compensation be received; and in which the association of electricity and civil suits is of common occurrence, the results of the experiments of Oliver and Bolan, carried on during the past year, and published in the *British Medical Journal* are of considerable interest. These experiments have been made with a view of ascertaining the cause of death after electric shocks, and the report includes a large amount of research into the effect upon animals of the alternating current in varying doses. The paper is illustrated by a number of records of the blood pressure, pulse and respiration of animals; before, during and after the application of the alternating current of varying voltage. They conclude as follows: "When an animal is exposed to electric currents of sufficiently high potential, death is, practically speaking, instantaneous. The animal is thrown into opisthotonos, during which breathing is suspended and the heart's action momentarily quickened and then arrested; if the current is strong enough it is stopped at once. On shutting off the current there occurs a deep inspiration usually followed by an expiratory cry. This has often been noted by workmen when one of their number has suffered a serious accident, and by it their attention is called to one who is found dead as the result of electric shock. Dogs through which an electric current has been passed, may on breaking the current, not only breathe spontaneously and rhythmically for several seconds, even a minute or two, but bark loudly; and yet all the time the heart has ceased to beat. In a few experiments death has been due to contemporaneous cessation of the action of the heart and lungs. Primary cessation of the heart's beat is without doubt the general rule; while under no circumstances have we succeeded in causing primary arrest of respiration followed by a failure of the heart. They also report the testimony of workmen employed in electric generating stations; who say that it is usual for men killed by electric shock to breathe a few times after life is otherwise apparently extinct. From the facts within their knowledge they conclude that death in the electric 'chair' must be instantaneous and without pain."

Cincinnati.

DRS. LAWRENCE CARR and WALLACE NEFF, have been appointed surgeons-in-chief of brigade with the rank of major.

THE following Cincinnati physicians attended the late meeting of the AMERICAN MEDICAL ASSOCIATION held at Denver: Drs. Holmes, E. W. Mitchell, Ransohoff, Zinke, Bruhl, Conner, H. M. Brown, Hilkowitz, French, Oliver, Wenning, Bonifield, Malsbury.

Dr. J. T. WHITAKER, professor of theory and practice of the Medical College of Ohio, has written a book on a non-medical subject, entitled "Exiled for Lése Majesté," elsewhere noted.

Dr. H. I. WOODBURN has been appointed professor of physiology and histology of the Miami Dental College.

San Francisco.

THE buildings of the Affiliated Colleges of the University of California are about completed and the moving in of the laboratory apparatus is now in process. The coming term of the Medical Department will open with the customary lectures at the old building, but the work will be transferred to the new quarters about the first of October. That this is to be the case, and that the work of completing the buildings and finishing the laboratories will not be dragged over many months unnecessarily, is entirely owing to the persistence of Dr. R. R. Beverly Cole, president of the Medical School, and a former president of the AMERICAN MEDICAL ASSOCIATION. He has devoted almost all his time to the superintendence of the work on these buildings for the past two years, and in addition to this by no means trifling physical work, has expended a good

deal of his own money upon the buildings. Dr. Cole suffered from an attack of partial hemiplegia, about nine months ago, but as soon as he could be out of the house he was again at the college buildings seeing that the work was pushed rapidly ahead, and that all particulars of the contracts were lived up to; indeed, it is probable that this work has kept him alive for more than a year, for his health has been failing rapidly during the last two or three years. It has been the hope of every one of the faculty that Dr. Cole might live to see his heart's desire, these magnificent college buildings, finished, and the Medical School installed therein. The move to the new quarters will probably have a most beneficial effect upon the college, for it has already shown some promise of this in the added interest in the laboratories and laboratory work. The recently created Electrical Department (established a little over a year ago) will be provided with a laboratory quite unequaled for its apparatus and facilities in this country, and it is anticipated that a very large amount of original research will be done therein. One somewhat novel feature will be a course of lectures on the most recent discoveries in the line of animal electricity, which will be delivered to all the classes and will also be attended by a goodly number of physicians as well. It is quite probable that the City and County Hospital will be located near the new building of the Medical School, in which event advantages of this department of the State University will be materially enhanced.

Philadelphia.

ABUSE OF CHARITY IN HOSPITALS.—As in all cities, the abuse of charity in Philadelphia has reached such a stage that the word "flagrant" may be properly applied, but one society after another has devised ways and means for its correction. Probably that one which will eventually prove successful is the one recently approved, which provides that persons applying for treatment shall give a statement as to their financial condition, income, etc., and having a statute enacted by the legislature making it a heavy penalty for any one guilty of making false statements. At the meeting of the Medico-Legal Society recently held here, and of which Dr. Samuel Wolfe is chairman, this subject was commented on at some length, and a plan is being formed by which an aggressive campaign will be waged along these lines in the early fall. It is then hoped to secure the indorsement of the County Medical Society and afterward have the co-operation of all medical bodies in presenting the subject properly before members of the State legislature.

PHYSICIAN AT HAHNEMANN HOSPITAL IN TROUBLE.—On June 29, a boy 14 years of age, while descending a ladder accidentally stepped on a nail, which ran into the center of his foot below the arch. He was taken to the Hahnemann Hospital, where the foot was dressed under an anesthetic. It is reported that he went again on two or three succeeding days and was told to come again at a certain hour July 5. On July 4 the boy received a wound of the limb by the accidental discharge of a cartridge and was taken to the Samaritan Hospital, where the part was dressed. The boy's limb was again dressed the following day, and as he informed those in charge of his engagement at the Hahnemann Hospital at 1 o'clock, he received attention early. In the lad's last statement it is reported that he reached the latter institution at a quarter to 2 o'clock, when the curator said to him, "My boy, you are too late, you were told distinctly to be here at 1 o'clock." It is said that other patients were being treated at the time, but the boy was sent away, and when he reached home was suffering great pain and had a high fever. A few days later he died of tetanus. After the boy was sent away from the Hahnemann, Dr. Cornelius, the family physician, was called in, but refused to accept the responsibility of the case and advised that Hahnemann physicians be notified. The father (a minister), on arriving at the institution, met one of the resident physicians in charge, who,

according to the father's testimony, became abusive. He stated that the object of his visit was to get some one from the hospital to attend his son, as other physicians would not take charge of the case. This the resident physician refused to do. All of these facts have been elicited before Coroner Ashbridge, and on asking the father, "Why did not the Samaritan Hospital doctors treat the wounded foot?" he was told that he did not know, but was under the impression that medical ethics prevented it being done. At the inquest the coroner stated to the jury "that the question to determine was from which wound the lockjaw had developed, but unfortunately, no autopsy could ever reveal that fact. While the evidence may point to the wounded foot as the cause, we can not determine that." On account of the connection of the resident physician in the case and of his abusive language toward preachers, the coroner censured him quite severely and thought that the hospital should take some action in the matter. The last accounts stated that the resident had resigned.

DR. GUITÉRAS PROSTRATED.—It is reported that owing to the excessive labors forced upon him on account of the campaign in Cuba, Dr. John Guitéras has been prostrated with fever and overwork. He reported 250 cases of yellow fever in the hospital at Siboney on July 16, and up to that time there had only been five deaths from that cause, thus proving the mildness of that disease. In the epidemic of yellow fever last year in the South, Dr. Guitéras also attributed the low death rate to the fact that, owing to a better understanding of that disease and of its symptoms than was formerly the case, many cases were recognized earlier and consequently received appropriate treatment before alarming complications arose, thus reducing the mortality.

BEQUEST.—By the will of Mrs. Eliza H. Frailey, widow of Commodore Frailey of this city, \$17,000 has been left to the Hospital of the Protestant Episcopal Church of Philadelphia.

A CASE OF SUSPENDED ANIMATION AT ST. MARY'S HOSPITAL.—On account of the death of his mother, Louis Holyworth, a young man of highly nervous temperament, fell into a state of unconsciousness when he lay in a trance for a period of about forty eight hours.

STAMPING OUT TUBERCULOSIS AMONG CATTLE.—According to the investigations of Dr. Leonard Pearson of Philadelphia, State Veterinarian, tuberculosis in cattle is rapidly disappearing and in many sections of the State the disease is very uncommon. It is stated that the older sections of the State suffered most, from the fact that more cattle were affected and, according to the provisions of the law, these had to be destroyed. About 30,000 cattle have been tested with tuberculin and in a larger number physical examinations have been made, and of these three thousand have been destroyed, thus getting rid of this many foci of infection.

STRANGE BEQUEST TO THE UNIVERSITY OF PENNSYLVANIA.—Edwin P. Kelly, an eccentric tailor who recently died in Philadelphia, inserted a clause in his will providing that after death a sufficient sum of money be set aside for converting his body into a mummy for the benefit of science, and that the same be presented to the University Museum. Owing, however, to the fact that the University would not receive the bequest, and to the fact that decomposition of the body had begun, this provision of the will can not be carried out.

THE PUBLIC SERVICE.

Assignments of Army Medical Officers.—To the 2d Army Corps, General Wm. M. Graham, Camp Alger, Va.: Acting Asst. Surgeons Isaac W. Brewer from Watkins, N. Y.; Frank W. Ross from Elmira, N. Y.; Joseph E. R. Ellis and Fred W. Palmer from Washington, D. C.; John C. Orr from Chambersburg, Pa.; Chas. V. Butler from Norwich, Conn.; John T. H. Slayter from Cambridge, Mass., and Jeremiah E. Leahy from Washington, D. C. To the 3d Army Corps, General James F. Wade, Chickamauga Park, Ga.: Major John P. Dodge, brigade sur-

geon; Major D. Appel, Surgeon U. S. A., relieved from the 1st division, 7th Corps, and the following acting assistant surgeons: John J. Repetti and Clark I. Wertenbaker from Washington, D. C.; Harry E. Gædler from Littletown, Pa.; John E. Bacon from Buffalo, N. Y.; John Mason Williams from Louisville, Ky.; H. L. Gilchrist from Cleveland, Ohio; D. R. Dewey from North Adams, Mass.; Chas. F. Craig from Danbury, Conn.; Chas. E. V. Kennon from North Easton, Mass., and A. E. Smith from Freeport, Ill. To troops at Tampa, Fla.: Acting Asst. Surgeons Urban S. Bird and Paul T. Dessez from Washington, D. C.; Jos. F. Ohmlecek from New York; Geo. H. Fox from Downingtown, Pa., and Hermann B. Gessner from New Orleans, La. To the 5th Army Corps at Santiago, Cuba, via New York City: Major Lawrence C. Carr, brigade surgeon, and the following acting assistant surgeons: Wm. T. Hamilton from Ironton, Ala.; Jas. T. Persons and H. B. Mohr from Mobile, Ala.; J. M. Newell, Ricardo Gaston, Jos. M. Pena, Clarence S. Perry, Wiley L. Akkey and E. Van Hood, all from Washington, D. C.; W. Edson Apple from Philadelphia, Pa., and John A. Lowner from Boston, Mass. Via Tampa, Fla.: Major Seaton Norman, Surgeon, 3d Volunteer Infantry; Capt. R. S. Woodson, Asst. Surgeon U. S. A., and the following acting assistant surgeons: J. R. Shannon from Washington, D. C.; Randall R. Hunter from Fulton, Kan.; George H. Fonde from Mobile, Ala.; Geo. E. Lawrason from Macon, Ga.; Frank R. Maura from Pensacola, Fla.; Milton Vaughan from Little Rock, Ark., and C. H. Tebault, Jr., from New Orleans, La. To the 7th Army Corps, General Fitzhugh Lee, Jacksonville, Fla.: Major W. S. Bryant, brigade surgeon, late Asst. Surgeon 1st Massachusetts Artillery; Capt. Benjamin Munday, Asst. Surgeon U. S. A., and Acting Asst. Surgeons Slids B. Post and John K. Rainey. To the U. S. general hospital, Ft. McPherson, Ga.: Major Wallace Neff, brigade surgeon, from Cincinnati, Ohio, and Major Wm. J. Wakeman, brigade surgeon, from duty at Camp George H. Thomas, Chickamauga Park, Ga. To the 1st general hospital, Chickamauga Park, Ga.: Acting Asst. Surgeons Chas. C. Marbury from New York City, Julius Ullman from Buffalo, N. Y., and Thaddeus Walker from Detroit, Mich. To the U. S. general hospital at Ft. Monroe, Va.: Acting Asst. Surgeon John R. Hicks from the steamship *Manitoba*. To the U. S. general hospital, Ft. Myer, Va.: First Lieut. Albert E. Truby, Asst. Surgeon U. S. A., recently appointed, from Otto, N. Y. To the U. S. general hospital at Montauk Point, Long Island, N. Y.: Acting Asst. Surgeon T. G. Holmea from Detroit, Mich. To the hospital ship *Missouri* at New York City: Capt. Alex. N. Stark, Asst. Surgeon U. S. A. Resigned: Majors Charles E. Ruth and Willia G. McDonald, brigade surgeons, and First Lieut. R. Mark, Asst. Surgeon, 3d North Carolina Infantry.

CHANGE OF ADDRESS.

Chance, B. K., from 1610 Christian to 118 South 17th Street, Philadelphia, Pa.
Corbell, R. L., from Chuckatuck to Port Norfolk, Va.
Caldwell, W. S., from Freeport, Ill. to Sioux Falls, S. D.
Freeman, B. F., from New Palestine to Ridgeville, Ind.
Golf, J. V., from Tuscon to Ashfork, Ariz.
Hodges, F. J., from Anderson, Ind. to Ashland, Wis.
Holland, J. W., from Holderness, N. H. to care The Checkley, Prouts Neck, Maine.
Zeller, J. O., from Ann Arbor to Skanee, Mich.

LETTERS RECEIVED.

ORIGINAL ARTICLES.

PNEUMATURIA.

Presented to the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY H. A. KELLY, AND W. G. MACCALLUM.
BALTIMORE, M.D.

During the last two centuries observations of the passage of gas with the urine have been made from time to time by various authors, and lately a number of very detailed accounts of this phenomenon have appeared. Brierre de Boismont in 1825 mentioned the spontaneous production of gas in the bladder and considered it due to a sort of flatulence or secretion of gas by the bladder mucosa. Roche confirmed this and Chomel added to the suggestion of gaseous secretion from the membrane, the idea that the gas might be due to fermentation. But up to 1860 practically all the instances were in cases of fistulous communication between the bladder and intestine, and when in that year Raciborski was called to treat a man who passed bubbles of gas from the urethra he first satisfied himself that there was no vesico-enteric fistula, before describing the case as one of spontaneous development of gas in the bladder.

The cases of pneumaturia may be roughly divided into three groups:

1. Those in which air is mechanically introduced into the bladder from without.
2. Those in which gas develops in the urinary tract through the agency of some fermenting organism.
3. Those in which there is a communication between the bladder and an air-holding viscus.

The first group is of little practical importance, as the discomfort is transient and the phenomenon has no pathologic significance. The introduction of air may occur during irrigation of the bladder if the apparatus used is not emptied of air before the fluid is allowed to flow. More commonly is the condition brought about by the knee-breast position occupied by the patient during the cytosopic examination as practiced by Dr. Kelly, when it forms the basis of the method of examination—the sagging of the viscera produces a negative pressure on the bladder walls which is neutralized as far as possible by the amount of air distending the bladder. After such examination when the patient is replaced in the dorsal position the air should be pressed out through a catheter, as otherwise the distention may cause considerable pain. The operation of lithotomy and the vesical operations are also sometimes followed by passage of gas into and out of bladder.

The second group of cases depends on the invasion of the urinary tract by some organism which by its action on the urine produces gas. In most of these cases the gas was produced in the urinary bladder, but in a few the kidney was evidently the seat of the

infection, and in one there was a general distention of the whole tract.

Since as yet we know so little of the etiologic factors in these cases we can hardly attempt any division of the cases on such a basis. Up to the time of Favre, who isolated an organism in 1888, no attempt was made to recognize the causative agent. Most of the cases described occurred in middle-aged or old men, where there had been for some time some obstruction to the flow of urine—such as an enlargement of the prostate or gonorrheal stricture—in others there were vesical calculi. In two cases there was paralysis following myelitis. Of the sixteen cases described nine were found to have glycosuria. The data are not sufficient to determine the reaction of the urine in all cases but the majority were acid up to the time when the determining factor of the pneumaturia appeared—that is the catheterization, sounding, lithotripsy, lithotomy, etc., one of which was performed in practically all the cases and was very quickly followed by the passage of gas. The reaction of the urine after the introduction of the organism by the catheter varies with the nature of the infection.

In three cases (those of Heyse, Guiard, and Pére) there is no definite history of catheterization before the emission of gas, but there was an increase in the amount of gas after such instrumentation, and it is now practically universally recognized that such introduction of the infection by means of instruments passed into the bladder is the essential factor in the production of pneumaturia of this type.

The various conditions described as existing previous to catheterization or sounding are predisposing causes. The residual urine present in the bladder when there is some obstruction to free egress forms a favorable medium for the growth of organisms and other slight infections, associated with the presence of an obstruction and atony of the bladder, or with the presence of vesical calculi, are often favorable to the invasion of the gas-forming organism. Further, stress has been laid by Guiard and others on the importance of the presence of sugar in the urine in the production of pneumaturia, and indeed in the sixteen recorded cases there was glycosuria in nine, with one more doubtful case. Guiard himself reports four such cases. Dumesnil, Ralfe, Müller, Senator and Pére report others. Of these cases the organism was recognized in only two, that of Senator, where there was a yeast, and that of Pére, where a bacillus resembling the bacillus coli communis was the gas-producer.

In sugar-free urines the formation of gas has been observed in several cases, and from the number Favre, Schow and Heyse have made detailed bacteriologic studies. The organisms described by these authors are almost identical, differing only in details, in which there is always some variation. They all belong to the group of which the bacillus coli communis is the type, and Heyse has identified the organism in his case

with the bacillus lactis aërogenes. Schow names the one found in his case coccobacillus aërogenes vesicæ. The following are the main characteristics of the three organisms; they are plump, short rodlets sometimes occurring in pairs: they grow aërobically on the various media, forming gas in the gelatin stab cultures and not liquefying the gelatin. Favre's bacillus is motile, Schow's slightly so and Heyse's non-motile. Favre's form shows an inequality in staining, suggesting the formation of spores. Urine media become alkaline after the growth of the organisms excepting Favre's, which produces acid. Heyse's bacillus is said to produce acid also by changing lactose into lactic acid. The organisms are pathogenic to rabbits. Heyse's also to guinea-pigs and mice. The gases produced are carbon dioxid, oxygen, nitrogen, hydrogen and marsh gas.

One of the cases in which the bladder was found distended with gas is described by Welch and Flexner. In this case the organism was the bacillus aërogenes capsulatus (Welch) which is distinguished by its size and aërobic growth. The gas produced was chiefly hydrogen and burned with blue flame.

As to the actual mode of formation of the gas we have various ideas. Guiard upholding his claim that glycosuria is the basis of all such pneumaturias, considers it an alcoholic fermentation, with the liberation of CO_2 , and thinks we should find alcohol in the urine, and this has been actually done by Senator, who found in the case where a yeast was the aerogenic factor alcohol in the urine and CO_2 as the gas.

Obviously this is the explanation of the decrease in the sugar in the urine of diabetics after the beginning of a cystitis, and the formation of the fatty acids as an extension of the process explains the acidity of the urine in such a case.

In the cases where the urine is sugar-free the analyses of the gas produced have showed the presence of CO_2 , and $\text{H}_2\text{N}_2\text{O}$, and CH_4 have also occurred, but it is suggested by Senator that these are absorbed merely from the blood. Just what is decomposed in sugar-free urine by the organisms is still doubtful.

The quantitative analyses vary so much that it is difficult to draw any general conclusions from them. In all, however, hydrogen forms the main bulk.

Other suggestions are offered as to the formation of the gas. Ralfe thinks that during the formation of acetone from aceto-acetic acid in the urine of diabetics gas might be developed. Kehler, indescring a case of hydronephrosis in which the hydronephrotic sac was distended with gas, suggests that from the remains of the kidney tissue normal acid urine was secreted at intervals and that this set free the CO_2 from the carbonates in solution in the stagnating urine in the sac.

The symptoms in these cases are not very striking. There may be continual desire to urinate, but it is rather a result of the cystitis than of the presence of the gas, which collects in rather small amounts. The passage of the gas per urethra causes no pain, but rather a tickling sensation, and is accompanied by a souffle or even by a distinct explosive report, or a musical sound. The bladder tympany may extend almost into the umbilical region at times, but unless the patient be actually inverted, the curve and situation of the urethra is such that no gas passes until after most of the urine has been passed. The gas may pass in such large bubbles as to give rise to intermissions in the flow of the urine, or if in very small

quantity it may merely form froth at the end of micturition.

Recovery occurred in practically all of the cases, the urine clearing up and again becoming acid; treatment with antiseptic lavage often greatly hastened this. The fatal termination of a few of the cases was due rather to infection of other organs than the bladder—pyonephritis with uremia.

Rather distinct from this class of cases is the group forming perhaps part two of the second division—those cases where the gas is produced in the kidney and ureter rather than in the bladder itself. Of such cases three have been reported, and a fourth has occurred during the last year at the Johns Hopkins Hospital in my own clinic. LeDentu in his textbooks cites a case observed by Lannelongue in a child aged 8, where there was a voluminous tumor in the right flank, at first mistaken for the liver. On aspiration 500 c.c. of a greenish fluid was obtained, together with a gas composed of oxygen, nitrogen and carbon dioxid. At autopsy the tumor was shown to be a renal cyst. LeDentu himself performed nephrectomy in a case where there was a renal calculus and an accumulation of gas in the kidney. This gas, as in the case of Lannelongue, was composed of oxygen, nitrogen and carbon dioxid, and he gives it as his opinion that the gas was absorbed from the blood. In the case of Tisné there was pyonephritis, with formation of a perinephritic abscess following obstruction from an enlarged prostate; evacuation of the abscess put an end to the discharge of gas from the bladder. The history of the case observed at the Johns Hopkins Hospital is briefly as follows:

Mrs. J. H., aged 36, married fifteen years, II-para, normal labors. About four months after marriage noted pain on urination. Two years later began to pass minute white calculi and during the next four years passed three larger calculi with much pain. At present has pain and swelling in left lumbar region and constant pain in bladder, especially just before urination; the urine always contains pus; for one year has passed gas from urethra in large amounts. Left kidney is felt as a hard tumor the size of two fists.

Cystoscopic examination. No. 10 cystoscope. Bladder mucosa normal. Right ureteral orifice easily found and normal in appearance and the urine clear issuing from it. The left ureteral orifice found by seeing issuing from it pus and gas bubbles. This was wiped away and the ureter easily discovered surrounded by a reddish area. On pressure over the kidney pus could be squeezed out of the ureter, and mixed with the pus were numerous air bubbles. On attempting to pass a metal catheter, a stricture of the lower portion of the ureter was discovered. A flexible, wax-tipped one and one-half mm. catheter was easily passed on first attempt and entered to the kidney; no scratch marks on the wax. Pus withdrawn was thick, viscid and of a foul odor.

Nephrotomy was done and a drainage tube inserted into the kidney, after evacuating the gas and washing out the pus which was found in its cavity. The patient made an uninterrupted recovery.

Cultures from the kidney were not definitely successful in isolating a single organism. Coverslips from the pus showed various forms, slender bacilli in chains, stout bacilli in chains and groups of cocci or short bacilli beside diplococci resembling the pneumococcus. The cultures showed mainly coccal-like organisms which did not liquefy gelatine, although the growth was here, as on agar, abundant; litmus milk decolorized and coagulated with the formation of acid; no formation in lactose agar nor in urine lactose agar. Scant growth on potato and in bouillon, the bouillon becoming clouded.

In the last group of cases the gas reaches the bladder through a fistulous communication with some air-holding viscus, which is in the great majority of the cases the intestine. Observations on such fistulas have been rather numerous, and the literature has grown to a considerable extent, especially in the last

fifty years. Among the most important publications are those of Blanquinque and Harrison Cripps, the latter of whom reviewed sixty-three cases in the literature. Chavannaz within the last few months has written very fully on the subject, considering, however, only such fistulas as occur in men.

Communication between the bladder and intestine may originate in the most various ways, and the cases may be roughly divided as follows: 1, congenital fistulas; 2, cases of traumatic origin; 3, cases in which the fistula results from necrosis of tissue between the cavity of the bladder and that of the intestine.

Savoy and Minich have described cases of atresia ani in very young children, in which the intestinal contents were evacuated through the bladder by way of a fistulous connection between the bladder and the rectum. This was probably a congenital malformation rather than the result of the accumulation of the feces. Treatment by the restoration of the natural anal orifice resulted in the cure of the condition.

Traumatism plays a relatively small part in the production of vesico-enteric fistulas, and the fistulas so formed are much more amenable to treatment than those in which the formation is associated with a diseased condition of the adjoining tissues. Billroth and Fischer have reported cases in which passage of gas through the bladder followed wounding of the rectum in lithotomy and in the cases reported by Dittel, Johnstone and Canton the fistulous perforation was due to violent catheterism. Gunshot wounds, stabs, protracted labors and retention catheters have been the cause in other cases, but by far the most common, traumatic origin seems to be in wounds of the rectum caused by falling on some sharp object, which, entering the rectum, passes through the intervening tissues into the bladder.

The tissues being in good condition, healing often takes place if the patient is merely kept at rest and the bladder and rectum kept as free as possible. In most of the cases frequent catheterization or the introduction of a retention catheter has been resorted to. Chavannaz states that the traumatic cases form 13.86 per cent. of all cases in men, but if we consider the fistulas in women, also, this is a rather too high estimate, and the figures approach more nearly to 11.4 per cent. of all cases.

The non-traumatic fistulas are produced by the necrosis of tissue between the cavity of the bladder and that of the intestine, after these organs have become adherent or by the necrosis of the walls of these organs, so that communication is established through an intervening cavity, such as an abscess cavity.

The old division of these cases into cancerous, tuberculous and inflammatory is adopted by Chavannaz, but it is sometimes rather misleading and the dividing lines can never be sharp. In almost half of the cancerous cases the cancer is only indirectly the cause of the fistula in that it forms a stricture of the intestine, the fistula being produced at a higher level. Chavannaz in his statement that the cancerous cases form more than 20 per cent. of all the cases seems to overlook this—the percentage of fistulas actually due to the breaking down of a cancer, involving both bladder and intestine, is probably under 10 per cent. Several English authors, Hunter, Blizzard, Heuston, Richardson and others have described such cases where the fistula was directly due to the invasion of the bladder wall by the carcinoma, and the subsequent

breaking down of the mass. Tavignot, Peron and Czerny have also described similar cases.

Stricture of the rectum seems to have a very important influence in the production of fistulas, whatever may be the origin of the stricture, although no writer has laid especial stress on this point. The intestine above the stricture becomes distended and feces stagnate there; indeed a complete lining of feces may be formed with a secondary lumen through which the liquid stools pass, and such stasis, combined with the severe straining at stool to produce an inflamed condition of the intestinal wall and peritoneal adhesion, are followed by ulceration through the wall into the adjoining bladder. Foreign bodies which have become lodged above the stricture often aid in this process.

From the side of the bladder the causation of fistula is very doubtful. Stricture of the urethra has probably only a predisposing influence in causing cystitis, etc. Mercier describes two cases in which the autopsy showed that ulceration had occurred at the bottom of several of the sacculations or cellulæ in the bladder wall, and that communication with the intestine had originated in this way.

Calculi have been said to ulcerate through the walls, especially if they have become lodged in depressions, but as Chavannaz remarks, they are more probably the result than the cause of intestino-vesical fistulas. Further, fistulas have been ascribed to the long-continued use of stiff retention catheters and sounds, necrosis of the vesical wall occurring where the beak of the sound pressed upon it: also to the presence in the bladder of long, hard, foreign bodies introduced from without for various purposes.

Probably the largest group is formed by those cases where at autopsy there is no stricture of the intestine nor any carcinomatous mass, but instead peritoneal adhesions between one or more loops of intestine and the fundus of the bladder, with perforation at the point of adhesion. These adhesions may be limited to a very small area, merely forming a thick wall for the fistulous tract, or they may be very extensive, matting the intestines. Flanner describes such a case where the matting was due to a tuberculous peritonitis and Robouam another where, among the coils of adherent intestine, there was a large abscess cavity communicating with the intestine and with the bladder. Frequently the communication is not direct, but through a space walled up by adhesions from the peritoneal cavity in which there is a collection of intestinal contents, urine and pus, and sometimes foreign bodies. Chavannaz has found such a *foyer intermédiaire* in 22.10 per cent. of the cases. The course of the fistulous tract is thus not always direct; in some cases the openings are directly opposed, in others the canal is long and tortuous after running for some distance between the coats of the intestine and bladder. This disposition may result in a valvular action of the fistula so that materials can pass only one way.

Fistulas have resulted in various other ways. Rupture of abscesses in the pelvis, into the bladder and intestine, has occurred in a considerable number of cases. This is especially frequent in women, where tubal abscesses and other suppurative processes in the pelvis are common. In men, somewhat similar conditions have occurred, sometimes originating in inflammation of the appendix, although when we consider the number of appendix abscesses that are seen

it is somewhat remarkable that in Chavannaz's statistics the appendix is concerned in the formation of such fistulas in only one case or 1.85 per cent. Very recently Fowler of New York has reported a case in which an appendix abscess was probably the cause of the fistula.

Connection of the two organs by means of an adherent cystic ovary has been described by Simpson, and in an inaugural dissertation Giessler described the formation of communication between the bladder and intestine after the rupture of an extrauterine pregnancy, with discharge of fetal parts through the various channels. Finally, Schoepffer relates the case of a child in which the breaking down of a small-celled sarcoma of the intestine, which had become adherent to the bladder, gave rise to the passage of intestinal contents into the bladder.

Another class of cases originates in tuberculous and suppurative processes in the tissues between the rectum and the bladder. Tuberculosis of the prostate passing into cheesy degeneration with discharge both ways is the basis of several cases; while gonorrheal abscess of the prostate and neighboring tissues may have a similar result.

The situation of the orifice of the fistula is rather important in determining the symptoms and governing the treatment. Chavannaz's statistics are as follows, in the cases in which the point was determined by autopsy: In 44.44 per cent. the communication was with the rectum; in 24.07 per cent. the communication was with the sigmoid; in 11.11 per cent. the communication was with the colon; in 7.40 per cent. the communication was with the colon and ileum; in 1.85 per cent. the communication was with the appendix.

The intestinal as well as the vesical orifices may be multiple and may be situated in different sections of the intestinal canal. This of course complicates greatly the operative treatment, and in the intraperitoneal treatment of such cases the question arises as to whether it is better to resect the intestine or to perform a number of lateral sutures. It will be readily seen that since the rectovesical fistulas form such a large percentage of the cases we may expect to find the majority of all the cases in men, and indeed Chavannaz's statistics uphold this in showing that 70 per cent. of all the cases were in men.

Affection of the kidneys is relatively uncommon, the bladder seeming to act as a protection against the passage of the infection up the ureters. Purulent and ammoniacal cystitides may, however, occur, and obstruction, due to the blocking of the urethra by the fecal matter is not infrequent.

The symptoms vary with the nature and origin of the lesion. There may be no symptoms whatever previous to the passage of gas, and later of feces, from the urethra, or frequent and painful micturition may occur during the formation of adhesions and the general signs of a local inflammatory process may be present. Passage of gas is always the most constant symptom and may precede the passage of fecal matter through the urethra. Of course pneumaturia is not an invariable accompaniment of vesico-enteric fistula; all the material transmitted by the fistula may pass the other way and we may have clear urine and urinous stools. Indeed, the passage of urine per rectum is very common, and especially noticeable when the intestinal orifice is low in the large intestine. The urine in the intestine may cause a diphtheritic inflammation of the mucosa, giving rise to a constant

diarrhea. The passage of gas into the bladder is rarely perceived, but in some cases it may give rise to an immediate desire to urinate. From the urethra it may be passed with wheezy or even with a loud noise; indeed, one patient described by Wegscheider, was nicknamed "die Luftschifferin" on that account. The quantity is variable, but the odor is generally fecal, unless, as in the case of Jewett, the opening into the intestine is very high. It generally appears at the end of micturition and is sometimes affected by the position of the patient, being passed only when he is in the erect position, etc. Fecal material passes with the urine in variable amounts, sometimes enough to form a slight granular sediment, sometimes in such mass that the urine has the appearance of thick soup. At other times the fecal material may form more solid masses or be forced through the urethra in cylindrical moulded lengths. Foreign bodies, such as bones, seeds, etc., sometimes pass through the urethra, causing great pain. Ascarides have been passed at intervals in some cases, notably that of Krachowizer, and thought to have been the cause of the fistula, but other authors have suggested that it is more probable that the ascarides merely took advantage of the already formed fistula. When the opening is high up in the intestine the intestinal contents, as they reach the bladder, may, as in the case of Jewett above referred to, be so little changed that the whole food of the patient can be recognized. The discharge of fecal matter through the bladder may be intermittent, ceasing for days at a time, or appearing only when the intestinal contents are fluid, as for example after a purge. The gas is, however, rather more constantly passed. Micturition may be frequent and painful although many patients have no pain whatever.

The stools are very frequently affected by the connection of the intestine with the bladder, there often being a continual diarrhea. In some cases a formed stool may be followed by a completely liquid one, the sphincter being able to retain the fluid which has reached the intestine, so that a large amount passes at once at stool, instead of a continual dribbling. The symptoms are fairly well illustrated by the following cases, which occurred lately at the Johns Hopkins Hospital:

Case 1.—Mrs C. A., aged 60, came complaining of the passage of gas and feces through the bladder. Her family history and early personal history throw no light on the present illness. In February, 1896, she began to have a pain in the lower abdomen; urine was thick, with a brown sediment, and very offensive for the first two months. Gas began to appear with the urine in June. In July, being constipated, she took licorice powder and the resulting movement passed through the bladder; was better then for a time. In October she submitted to an operation for the cure of a suburethral abscess. For several months the passage of feces ceased. In April, 1897, it grew worse and she passed a great deal of feces and gas with the urine. In July the discharge ceased a little, gas occasionally present. In November had severe attacks of intestinal pain and passed from the bladder what she thought was its lining. Since November the discharge has been rather less up to January, 1898, when it grew worse again. The presence of gas in the bladder was associated with a continual desire to urinate—never was there any pain from distension, however. The gas was discharged with a loud sound easily heard by those in the room or even in the next room. It had a fecal odor. Sometimes some pain in the abdomen on passage of gas. Not much pain in urethra except when the suburethral abscess was present. Controlled the gas as she did the urine. Since January has passed a great deal of feces through the bladder, the amount being increased when the bowels do not move with sufficient frequency. The urine showed the presence of a brownish sediment containing striped muscle tissue, partly

digested vegetable shreds, starch, an egg of trichocephalus dispar, pus, granular and hyaline casts. Cultures and cover-slips showed the intestinal bacteria. The urine contained albumin and an increased amount of indican.

On administration of bismuth subnitrate by mouth the characteristic black crystals of bismuth sulphid appeared in the urine. So also injection of a blue solution per rectum colored the urine blue.

Cystoscopic examination of the bladder gave the following: A No. 11 speculum introduced and bladder expanded to 63 cm. from internal urethral orifice to posterior wall.

In the posterior hemisphere the capillaries are much increased, this increased capillary vascularity becoming more marked toward the base of the bladder, where there is a uniform rosy injection.

Irregular deposits of pus over the base of the bladder, which is deeply injected. A No. 13 speculum introduced and a calculus extracted with mouse-tooth forceps, together with two small bits. In posterior hemisphere on the left, at the junction of the upper and lower quadrants, is a puckered surface extending slightly crescentic upward (knee-chest position) with its canal directed upward and backward about 8x3 mm. The borders are deeply injected over an area about 3 to 5 mm., but beyond this the surrounding tissue is comparatively normal.

Right ureter is deeply injected around its orifice and almost exactly in the median line; the left ureter is displaced to the left. There is around the right ureteral orifice a membranous deposit almost pure white, and cover-slip from this showed it made up of short bacilli and pus cells.

Rectal mucosa normal.

At operation the sigmoid flexure of the colon was found adherent to the bladder at the vertex on the left side. Area of adhesion 2.5 mm. in diameter, free on all sides so that the finger can be hooked under it, lifting it from the pelvis.

The two organs carefully dissected apart, protecting the peritoneal cavity with gauze; fistula 2 mm. in diameter cut through. Vesical orifice brought together by means of interrupted catgut sutures making a line from above down and to the left 4 cm. long. Dense fibrous tissue was then cut off the rectum, and mucosa lining the fistula cut out, making the opening into the bowel about 2 cm. long, with shelving sides in healthy tissue, this also closed with interrupted silk sutures about 2 mm. apart. Salt solution irrigation of the peritoneal cavity. Abdomen closed without drainage. Bladder drained by retention catheter and occasionally washed out.

The patient made a perfect recovery, the urine clearing up at once and the passage of gas ceasing immediately. Convalescence has been uninterrupted.

Case 2.—Miss J., aged 57; admitted to the Johns Hopkins Hospital in November, 1890. Menses regular up to age of 48. At 42 had swelling of legs with vaginal hemorrhages; since age of 50 these have occurred at intervals. Have grown worse lately.

Right and left tubo-ovarian masses made out. Celiotomy was performed and the tubo-ovarian cyst on left side dug out of adhesions in lower part of pelvis. Cyst ruptured, discharging 30 c.c. of thick, sticky, mud-like substance. Right tube and ovary also removed; foul odor suggested an opening into bowel. Pus discharged from uterine cavity came from a tumor in the body of the uterus.

Patient recovered. In March, 1896, she was readmitted, complaining of general pelvic pain. Vaginal puncture was performed, evacuating dark fluid blood and clots from a sac between uterus and bladder, puncture being performed in front of the cervix.

She was then passing bubbles of air at the end of micturition and there was pus in the urine. Cystoscopic examination showed an orifice 1.5 mm. in diameter in the left lower quadrant of the posterior bladder wall, from which pus exuded; a sound was introduced about 1 cm. into this. In March, 1898, at age of 64, she consulted Dr. Cullen, who found on examining the bladder a slight injection around the trigone and a marked reddening above and to the left side; no opening could be made out, although bubbles of gas and particles of feces could be seen coming from the injected area. Injection of milk into the rectum appeared at once in the bladder. March 23 the abdomen was opened and the upper left side of the bladder found firmly attached to the rectum just at the pelvic brim. The adhesions were gradually separated and a firm cord 1.1 mm. in diameter found connecting the gut with the bladder. This was cut through at the expense of the bladder wall. The edges of the rectal opening were then turned in and the wound closed by two rows of mattress sutures. Vesical opening similarly closed. The patient did well for twenty-four hours, but her weakness was such that she succumbed. There was no peritonitis nor hemorrhage.

In this case it is probable that the stump of the left tube had become adherent to the rectum after the removal of the appendages eight years before, and that in this way the bladder was drawn up snugly against the rectum. Adhesions soon formed, and the fistulous opening followed in the same way that a dermoid cyst may become infected from the intestine after adhesions have formed.

The diagnosis of the condition is generally easy. Passage of gas, together with fecal material, is practically pathognomonic of the existence of fistula, although the passage of gas alone is not so. The blackening of a silver sound in the bladder occurs also in those cases of hydro-thionuria described by Rosenstein, Scott and others, so that that test in showing the presence of sulphuretted hydrogen, does not necessarily demonstrate the presence of a fistula. Colored injections into the rectum or into the bladder have been used very frequently, and when they give positive results are important. The most useful of these solutions are those in which the coloring matter is in suspension, rather than solution, as some materials such as methylene blue are readily absorbed and secreted in the urine. Milk, suspension of carmine, prussian blue, etc., have been used. In other cases solution of some easily recognized chemical such as the salts of iron, have been injected and the urine appropriately tested. Exploration of the bladder by means of a sound does not give the certain results ascribed by some authors, but rectal examination is of extreme value in many cases. Chavannaz lays stress on the bimanual recto-abdominal palpation. Perhaps the most important of all is the direct cystoscopic examination either by means of the Nitze-Leiter cystoscope, or better by inflation of the bladder with air and direct examination with the vesical speculum, as was carried out in the cases just reported.

The gravity of the prognosis depends, to a great extent, on the etiology, position and size of the fistula. Generally speaking, those of traumatic origin much oftener terminate favorably than those of inflammatory origin; indeed, there are reported several cases of healing after a mere rest treatment. In the carcinomatous and tuberculous cases the mechanical results of the fistula are superadded to the effects of the primary disease. In the cases of intestinal stricture the prognosis is modified by the presence of the stricture, which limits the operative measures for the cure of the fistula. In many of the cases where the fistula is small and does not transmit a great deal of material to the bladder, the patient may live years in comfort; the passage of gas alone with the urine may go on for a very long while without any inconvenience, but when the opening is larger there is constant danger of obstruction of the urethra and choking of the bladder with feces; uremic symptoms may develop followed by death. Renal symptoms are comparatively rare when we consider the condition of the bladder. The formation of a sac in the course of the fistula between the bladder and intestine adds greatly to the gravity of the prognosis, as there is an accumulation with absorption of toxic substances.

Apart from the mechanical results the general health may be disturbed. When the fistula is high up nutrition is interfered with in so far as the contents of the upper intestine pass through the bladder instead of through the remaining intestine. Vomiting, fever, insomnia, symptoms of intoxication may appear and death may result from general exhaustion or from acute peritonitis.

Treatment is palliative or curative. Palliative

treatment consists in such general measures as promote the comfort of the patient by decreasing the amount of fecal discharge in the urine, and keeping the rectum and bladder washed clean. A rigid régime of food producing but little feces should be observed; the patient may be kept in a position such that gas only passes into the bladder. Iliac colostomy may be considered palliative; like enteroanastomosis, it has in some cases proved curative, as reported by Pennell, Holmes, Bryant and others.

Curative treatment is in most cases operative. The operations that may be performed in cases of vesico-rectal fistula are more numerous naturally than those suitable for fistulas into the intestine higher up. Briefly these methods are, as described by Chavannaz:

1. The rectal method in which the edges of the fistula are freshened and sutured through a speculum inserted into the rectum.

2. The transvesical, in which an extensive suprapubic cystotomy is done and the vesical orifice sewed up after freshening the edges, the sutures being knotted inside the bladder.

3. In the perineal method a dissection is made through a perineal wound, separating the rectum from the prostate and reaching the cul-de-sac; freshening and suture of the fistula is then carried out if practicable.

4. Resection of the sacrum with a gradual separation of the rectum has been advised.

5. The transpelvic operation with an incision through the pubes, or symphyseotomy and subsequent dissection backward.

6. Most satisfactory of all, both for intestinal and rectal fistulas in the hands of an experienced surgeon, is the transperitoneal method described in detailing the case of Mrs. A., although there are some cases where the fistulous tract is deeply sunk in the pelvis, where this method would be very difficult to apply.

THE ASEPTIC ANIMAL SUTURE: ITS PLACE IN SURGERY.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY HENRY O. MARCY, M.D., A.M., LL.D.

BOSTON, MASS.

Modern surgical technic differs in such a marked degree from the methods of even a recent period, that it is not a wonder that great differences of opinion still exist in regard to many questions pertaining to the treatment of wounds. For the present, at least, certain conditions of fundamental type may be accepted as settled, so far as the theory, or ideal, aimed at is concerned; for example, a wound made in aseptic, well-vitalized tissues, and maintained aseptic will be followed by primary union. It is not my present purpose to discuss the methods for maintaining a wound aseptic only so far as pertains to its closure and subsequent protection.

In any considerable wound it is necessary to occlude blood vessels and rejoin the separated structures. This must be done by the use of ligatures and sutures. The material best adapted for this purpose is the subject of the present inquiry. The materials in use are, thread made from hemp, linen or silk, almost exclusively the latter; metallic sutures, iron, gold and silver; silkworm-gut, catgut, and the tendon of animals, especially that from the tail of the kangaroo.

The silk fiber, spun, twisted or braided in various sizes, is so manifestly superior to the vegetable fibers

of cotton, hemp and linen, that only silk merits discussion. Silk has continued in more general use as a ligature for the following reasons: It is strong, is manufactured into a thread that is very smooth and even, can be readily sterilized by wet and dry heat, is comparatively cheap and easily obtained in any desired size. Until it was found possible to close and seal wounds without drainage, silk seemed the ideal material for ligatures and sutures. Then it was supposed necessary to remove both ligatures and sutures, no matter how applied. When it was shown to be unnecessary and even harmful to drain aseptic wounds, the inquiry naturally arose, can not some material be found for sutures which will remain in the tissues sufficiently long to serve the purpose of constriction or coaptation, and ultimately disappear under the influences of the vital processes of the surrounding structures?

So far as the ligation of the larger arteries is concerned the problem thus presented is by no means new. The most important of the original studies in this direction of an early type were conducted by Dr. H. G. Jameson of Baltimore, and his prize essay published in 1829, upon the closure of arteries in continuity by the use of the animal ligature is worthy of commendation as a contribution of the highest scientific importance. It is singular to note that many of the leading surgeons of this period accepted his teachings as of great value, and ligated arteries as Dr. Jameson directed, using for material, more commonly, carefully prepared strips of buckskin. These were experimented with, somewhat, by English surgeons and met the approval of even Sir Astley Cooper. The directions were explicit, to ligate so as to occlude, but not to devitalize the artery, cut short and leave the ligature in the deep part of the wound.

The list of experimental studies published by Dr. Jameson demonstrated that the result of such ligation in the calf, dog and sheep caused a permanent occlusion of the artery, that the foreign material was encapsulated by living cells, and that ultimately the ligature entirely disappeared, leaving in its place a permanent reinforcement of connective tissue.

However, all this valuable experience was lost and forgotten in the heated controversy over the so-called inflammatory processes in wounds, which promised a fruitless and endless discussion, until the masterly studies of Lord Lister demonstrated the cause of the same to be vital and extraneous. He naturally arrived at the theoretic conclusion that, in a non-infected wound, the vital processes would be ample to permit of the safe application of an absorbable ligature for the constriction of an artery. So far as I know, Mr. Lister was utterly ignorant of the demonstrations of Dr. Jameson referred to above, and as the laws of England at that time were so framed that studies upon the lower animals, even of such an important character, were not permitted, this great master was obliged to resort to France for the privilege of pursuing his investigations. His conclusions are almost identical with those of Dr. Jameson. He used for ligature material, however, catgut as furnished for musical instruments, steeping it in a strong carbolic solution in order to render it antiseptic.

So far as I am aware it had not occurred to any to make use of sutures deeply implanted in wounds, buried, until in 1870, when it became very evident to me that it was necessary for the purpose of curing hernia to close separately the different structures of

the abdominal wall and to restore the inguinal canal to its normal oblique direction.

Based upon the knowledge of the animal ligature left *in situ* about an artery, it seemed a logical deduction that this could be safely effected. I instituted at once a series of comparative studies in order to ascertain if such suturing was safe and trustworthy. My investigations proved conclusively that aseptic animal structures buried in well-vitalized tissues were surrounded by leucocytes, which, little by little, invaded the material used and *pari-passu* were themselves transformed into connective tissue-cells, taking in a considerable degree the shape and direction of the suture material. So noteworthy was this, that at first I was constrained to believe that the material itself became revitalized as a sort of graft, but more careful observations demonstrated that the foreign material disappeared by a process of absorption, leaving in its place a vitalized band of connective tissue, the resulting product of which, in certain conditions, proves to be of the greatest value, to-wit, where the integrity of the parts are liable to damage because of tension, e. g., as in hernia and all wounded structures subject to special mobility. It gradually became evident that a careful coaptation of wounded tissues could be safely made, thus avoiding pockets of blood or serum, and, as a consequence, do away with the use of drainage-tubes, then supposed absolutely essential.

The drainage-tube in *aseptic* wounds can be only a damage and used as the least of two evils, since so much of the wound as is occupied by the tube must necessarily be left open, and closed by processes of a much slower character, so-called secondary union. Again, too, it was soon demonstrated that, notwithstanding the extraordinary precautions taken in the use of antiseptic dressings, a considerable percentage of wounds in which the drainage-tube was used, although aseptic so far as operative measures were concerned, became septic from the introduction of infection along the canal of the drainage-tube, more commonly due to the ever-present bacteria pertaining to the skin.

One of the most interesting and profitable original studies made in the Johns Hopkins Hospital was the demonstration of the micrococcus pyogenes albus as the normal habitant of the dying epithelium of the skin and their causation of so-called stitch abscesses, when the suture included the skin. Now the deduction seemed clear that an aseptic wound to remain aseptic must be coaptated so that pockets can not develop for the undue accumulation of fluids; that the drainage-tube should be abandoned, and that even the skin itself should be closed by a sub-cuticular suture in order to avoid skin infection. Then it was apparent that in the devising of the sub-cuticular suture in order to avoid stitch abscesses I had acted wiser than I then knew, and that the ideal dressing should consist of an hermetic seal so absolute as to prevent the possibility of extraneous infection. This is found in collodion, the contractile preferred, to which is added a small percentage of iodoform, reinforced by a few fibers of absorbent cotton, which admirably accomplishes the purpose while it still further fixes and holds at rest the evenly coapted edges of the skin and minimizes the cicatricial line of repair. Oftentimes a cicatrix is traced with difficulty some weeks after the union of such a wound, a result, which upon certain parts of the body, for esthetic purposes is of the highest importance. Having worked out, by slow process of

detail, the above conclusions and published¹ the results from time to time, I now thought it was of the first importance to demonstrate the kind of suture material best adapted for this purpose, viz., buried sutures.

Material.—Silk is manifestly unfitted, since, to say the least, when aseptically implanted in the tissues, it rarely, if ever, disappears by a process of absorption, and not seldom after a long period of discomfort, the structures rid themselves of it, attended with a considerable amount of suffering, with injury to the surrounding parts.

When silk sutures are buried, it is unquestionably better that the thread should be as fine as can be used with advantage. The sutures should be interrupted and few in number. Even thus carefully applied, it often happens that weeks or months afterward these sutures are thrown off by a process of proliferation, although the wound has been made and maintained aseptic.

Silk buried in portions of the body called into special activity is most likely to give trouble. So well established are the foregoing objections to buried silk sutures that a general inquiry has arisen, is it not possible to substitute something better in its place? Although metallic sutures were at one time in very general use, for manifest reasons they have been discarded, until now they are limited to a very narrow range of possibilities. (Where it is necessary to make a permanent fixation of the osseous structures, the wire suture has an advantage, and here it is intended to be permanently left. Even under these conditions, when cut short and buried beneath the soft tissues, wire is very likely to be a source of subsequent irritation.) Silk-worm gut is absorbable in such a slow degree that it can be classed as belonging to the non-absorbable material used for ligatures and sutures, and for this reason is almost as objectionable as wire. The use of wire and silk-worm gut as a buried suture has its advocates for the most part among those who do not feel that animal sutures have a durability sufficient to be trustworthy.

I am indebted to Dr. Charles P. Noble of Philadelphia for a recent reprint of an article entitled, "Remarks upon the Use of the Buried Permanent Suture in Abdominal Surgery," published December, 1896. In it he states, "the original and simple method of a through-and-through suture for the closure of the wound in celiotomy has been tried and found wanting, because of suppuration and subsequent hernia. That he has had no experience with the use of catgut or other absorbable material in the closure of the celiotomy wound, because of the unfortunate results reported from Germany." He quotes Winter, who reports 8 per cent. of hernias following the use of the buried catgut suture. He also refers to the experience of Dr. Schede of Hamburg, who has employed silver wire as a buried permanent suture in the closure of celiotomy wounds since May, 1887. He thinks the favorable opinion of Schede is borne out by the experience in the Johns Hopkins Hospital where silver wire has been in general use for a number of years, with a low percentage of suppuration

and few subsequent removals of the buried sutures. He also refers to the experience of Dr. Edebohls of New York, who for a considerable period used silk-worm gut as a buried suture in the closure of the abdominal wall. Dr. Edebohls reports that from 5 to 10 per cent. of all his sutures thus employed caused suppuration and were either discharged spontaneously or required removal in order to secure closure of the wound or suppurating sinuses. In his aseptic wounds where primary union had taken place, suppuration followed in some cases in a few weeks, in others after some months, and in one after two years and a half. On this account Dr. Edebohls now uses chromicised catgut instead of silk-worm gut.

Dr. Nobe's object in writing his article is to show that in his experience silk-worm gut has proved a safe and reliable means of closing celiotomy wounds. He states, "that he has closed two hundred and ninety-seven celiotomy wounds by the use of buried silk-worm gut sutures with only seven cases of suppuration and with satisfactory results in preventing hernia." He emphasizes the selection of fine gut which is boiled for half an hour before each operation. The sutures are not tied too tightly and the ends are cut as short as possible. He used catgut for the closure of the peritoneum, the fatty structures and the skin as a continuous suture.

Dr. William B. Coley of New York reports² in detail sixteen cases where silk, silk-worm gut and silver wire were used as buried sutures for the cure of hernia. In these not alone was the hernia not cured, but suppuration supervened, and the sutures had to be removed. Of the number, five were closed with silk-worm gut sutures. He reports from the recent work of Schimmellbusch, page 121: "It has more than once been observed that in primary closure of wounds by silk or silver wire, the ligature, at the beginning well imbedded in the tissues, after a long period of time becomes repelled and suppurates out. The imbedded silk or silver wire simply remains as a foreign body in the tissues, of which the organism endeavors to free itself as soon as a favorable opportunity presents." He also reports: "In two hundred and fifty cases of hernia operations in which I have used kangaroo tendon for buried sutures I have not had a single instance of sinus formation, and the percentage of primary union has been ninety-six per cent." "The ideal suture, then, would be one that would hold the parts in apposition for eight or ten weeks and then disappear by absorption. In kangaroo tendon we have these conditions perfectly fulfilled. There has never been observed at the Hospital for Ruptured and Crippled a single case of delayed healing sinus when tendon or absorbable suture was used. Unless those who use and advocate silk, silk-worm gut or silver wire in hernia operations are able to present some advantages to offset the serious disadvantages that have been demonstrated, I believe these non-absorbable sutures should be entirely abandoned."

Chance furnished me the opportunity of being Lord Lister's first American pupil, and so great was my enthusiasm for the master that I accepted unquestionably his teachings of the value of catgut as a ligature. I prepared my own catgut ligatures for some years, according to his directions, and they were undoubtedly aseptic. It was not long, however, before infection followed the use of commercial catgut

suture material which was obtained from the most reliable sources. This led me to investigate anew with painstaking care the animal structures which might be better suited for this purpose. I soon ascertained that catgut is necessarily faulty for two reasons, first, as the connective tissue sheath of the small intestine of the sheep, it must necessarily be separated from the other coats of intestine by maceration. This is in reality a process of bacterial putrefaction. The connective tissue sheath being more resistant to the putrefactive bacteria, remains less injured by it, and as a consequence can be removed entire, but it is necessarily damaged by the processes involved. When thus separated and cleaned, although appearing as a white sheath of uninjured connective tissue, it is everywhere teeming with bacteria, and the cement substance which holds the connective tissue cells in fixation has been damaged by their action and by the necessarily long-continued maceration. So far as I am able to learn, at this stage of the process in the manufacture of catgut no thought of the value of sterilization has been entertained and no effort made for its accomplishment. The second objection to catgut as a suture material is the disposition of the connective tissue fibers themselves. For the physiologic necessity of dilatation and contraction of the intestine these fibers cross each other in a direction oblique to its long axis. The intestinal sheath is divided into strips more or less narrow in order to produce the desired sizes. When wet, it is an elastic, flat band with irregular edges. This is twisted upon itself into a cord and dried and thus is manufactured the catgut of commerce (strings originally designed for musical instruments).

Such is the extraordinary strength of the connective tissue that even thus disposed, when dry, catgut is very strong, but every musician knows the great care he must exercise in keeping it dry and keyed to the proper tension point. When damp it soon becomes soft, elastic and unreliable. When catgut is compared with the connective tissue found in the tendons of animals, the illustration is not overdrawn to say that the differences are as great as would result from weaving silk into the finest fabric, cutting it diagonally into strips and twisting it for use as a fishing line. When dry, it is comparatively strong, but when wet, a soft, elastic, flat band takes the place of the well-made fishing line. The surgeon must remember that his buried suture is ever wet since it is immersed in the fluids of the body. This is the reason that catgut swells so extraordinarily upon being soaked, that knots in catgut are unreliable, and the yielding of the ligature may be sufficient to prevent the closure of the enclosed artery. In the tendons of animals the connective tissue cells are disposed parallel to each other and held firmly in contact by the cement substance, which in the preparation of sutures should be injured as little as possible. Tendons should be taken from freshly killed animals and prepared so that infective decomposition never ensues. Their use as ligatures is not new. Paul Eve, the great surgeon of Tennessee, employed them in the ligation of vessels many years before Mr. Lister's study of the subject. He used the tendons of the deer, taken directly from the freshly killed animal.

However, the knowledge of the use of tendons for ligatures was unknown to me until after my first publications upon the subject. As the result of my investigation and research for good suture materials, I was

² New York Medical Journal, Feb. 29, 1891.

so convinced of their superiority that I contributed a paper upon the subject at the International Congress held in London in 1881. Tendons from the whale, the broad fascia of the back of the buffalo and moose (Indian thread) proved of about the same value as the long tendons from the leg of the moose, deer and caribou. Although less fatty they were little to be preferred to the tendons from the domestic animals. Good ligatures are comparatively easy to obtain from these sources, but suture material must be smooth, even, strong, fine and for a continuous suture, of considerable length to be of service.

After a prolonged research, I found that the tendons from the tail of a medium-sized kangaroo furnished a material which possessed all these requisites. The entire family of marsupials have the *psaos* muscle divided into fasciculi, each of which has its independent tendon, extending to the very extremity of the tail. These lie parallel to each other and are easily separated. In the larger kangaroo these tendons are not infrequently thirty inches long, but entirely too large for sutures. Many of them will split readily, but are never as strong or satisfactory as the whole tendon from a smaller animal. Much the larger amount of kangaroo tendon shipped for commercial purposes is naturally obtained from the larger species, since it is sold by the pound, and by far the greater portion of tendon in the market is consequently less valuable.

Good tendon is smooth, even, and of a tensile strength greater than silver wire of the same weight. It should be taken from freshly killed animals, quickly sun-dried, and kept dry during the period of shipment, and as a consequence, its sterilization is effected with much greater certainty and with less damage to the intercellular cement substance. The tendon from the variety called the Wallaby furnishes the best suture material, but so difficult is it to obtain first-class tendons, that out of a lot of one hundred and forty pounds recently sent me, scarcely twenty were of first quality.

Preparation and sterilization of catgut—The recognition of the advantages attendant upon the use of absorbable suture material has been so universal that a very great many different methods have been experimentally tried in order to furnish from catgut the so-called ideal suture. The very fact that so many different methods of preparation have been employed is an evidence that none of them have proved entirely satisfactory. Only recently Dr. Nicholas Senn³ of Chicago, has given his experience in the preparation of catgut. He approves Hofmeister's method of preparing catgut by the use of formalin. With this the profession is already familiar. The catgut is rendered tense by winding it upon a glass plate and immersed from twelve to forty-eight hours in a 2 to 4 per cent. aqueous solution of formalin; then immersed in flowing water for twelve hours to free the gut of the formalin, boiled in water from fifteen to twenty minutes, hardened and preserved in absolute alcohol containing 5 per cent. of glycerin and 1/10 of 1 per cent. of bichlorid of mercury.

Dr. Senn modifies the foregoing method by preserving the formalin gut, after boiling it, in absolute alcohol 950 parts, glycerin 50, finely pulverized iodoform 100 parts. He considers the iodoform of value as a mild antiseptic, and that it diminishes the amount of primary wound secretion. He speaks of it only as a

ligature, but I infer that he also uses it as a buried suture. He quotes from Nusbaum approvingly, "Catgut is without doubt Lister's greatest discovery," and states that he considers "the aseptic absorbable ligature as one of the greatest achievements of modern surgery." Dr. Ralph C. Larrabee of Boston in a recent article⁴ gives an interesting review of the sterilization of catgut by boiling in alcohol. He quotes Lauenstein's investigations,⁵ where, in a large series of cultures made for the purpose, he demonstrated quite a variety of micro-organisms as commonly present in catgut. Dr. Larrabee shows from his own experimental studies that boiling in 95 per cent. alcohol for one hour did not render the catgut sterile, and in each case he obtained cultures of a bacillus. Chemically, catgut contains water (23 per cent.) and fat (7.5 per cent.). By most of the recent processes of sterilization these substances must be removed. The remainder consists chiefly of collagen, which under the continued action of hot water is transformed into gelatin. Dr. Larrabee quotes the experiments of Saul, who found that if catgut was boiled in a 5 per cent. solution of carbolic acid in absolute alcohol, three hours were not enough to kill anthrax bacilli dried upon it. The addition of a small quantity of water gave much better results, since by using a 90 per cent. solution, instead of absolute alcohol, the bacilli were killed in ten minutes. Hofmeister has, however, found gut, after such boiling, contained staphylococci, which developed in proper culture media. As a result of Dr. Larrabee's investigations, he found that boiling the gut after Saul's method for fifteen minutes was sufficient to sterilize the smaller sizes, but, in forty experiments from the larger sizes, boiled from fifteen to thirty minutes, he obtained six cultures. He therefore concludes that it is necessary, in order to be absolutely sure of sterility, to boil the smaller sizes thirty minutes, the medium forty-five minutes; the largest sizes are safer boiled one hour. "Catgut thus prepared deteriorates by age, and whether preserved wet or dry, a certain per cent. of the actual strength is certainly lost."

Dr. R. M. Pearce reports⁶ a series of careful studies of sterilization of catgut with formaldehyde. This he applied by vaporizing small amounts of the 40 per cent. solution (formalin) into a glass chamber in which the catgut was exposed. In every experiment sterilization was satisfactory, but the gut became so brittle that it was ruined. He shows that the injury occurred largely from the moisture necessarily contained in the vaporized formalin. He found that the gas in a dry condition gave a much better result and this he recommends as a practical method of sterilization: "Nothing is required but a wide-mouthed jar, some paraform pastilles, a piece of wire gauze or open-meshed cloth and a wide-mouthed bottle. A dozen pastilles are put in the bottom of the jar and covered with a piece of wire gauze to prevent actual contact with the gut. The pastilles yield a sufficient amount of gas for complete sterilization."

Dr. A. Goldspohn⁷ of Chicago has contributed an interesting article upon the preparation of catgut by formalin and boiling. From a careful review of the experimental studies of a number of reliable investigators and a series of his own he deduces the follow-

³ Journal of the American Medical Association, Dec. 12, 1896.

ing: "These facts being known we must not depend on formalin to sterilize catgut but simply to harden it so that it may be boiled *ad maximum*. That this maximum boiling of twenty minutes may be possible it is necessary to remove all excess of formalin from the gut by prolonged washing in running water previously. But the vexatious question is now settled that catgut can be certainly sterilized, for we can now boil it in water, the ideal menstruum, as long as the adherents of silk need or usually care to boil that, and the advantages of absorbable ligatures are too obvious to require further comment. However, there is one slight objection to catgut remaining, which arises from the ptomains which it may sometimes contain. On this subject Dr. Edmondo Orlandi in Turin published researches in 1895, and Professor Papfert of Giessen likewise toward the close of 1896. Both affirm the occurrence of slight or non-virulent suppuration limited to the immediate vicinity of the gut, not producing any systemic disturbance, and usually subsiding without any marked detriment locally. However, to avoid this objection partly, I am now having all catgut soaked in ether previously for forty-eight hours or more, to extract the fat, hoping also to get rid of some of the ptomains that may be present."

"My reasons for preferring catgut so prepared are, first and chiefly, because it stands the crucial culture tests that have been applied to it by its founders, which is not true of any former method, that of von Bergman not excepted, for Braatz cultivated anthrax spores of only moderate resistance in abundance from catgut prepared by that method. Secondly, because of the immense satisfaction to a surgeon derived from a knowledge of the supreme germicidal capacity of water boiling for twenty minutes. Thirdly, because this catgut is hardened enough to answer the purposes of chromicized catgut reasonably well without being too hard. From clinical observations my impression is that the smaller sizes hold from seven to ten days, while the larger sizes, as No. 6, used on pedicles, etc., hold for about fourteen days."

Formalin acts upon connective tissue in a way to change its ultimate cells and cement substance into a homogeneous mass of gelatinous character. Deformalized in running water for twenty-four hours and boiled loosely coiled in water, the gut or tendon swells immensely and shortens to about one-third its former length. It is fibular, elastic, a homogeneous translucent mass. If wound tightly on a small test tube and boiled shrinkage does not take place, but the other changes ensue and the tensile strength is much lessened. If catgut thus heated remains in the tissues only as long as Dr. Goldspohn has determined, its durability is much too little to be trustworthy for many operative purposes.

In the present status of the question, the views of those who have, for a time at least, discarded the use of catgut as an unreliable suture material must be held to be justifiable.

In the *New York Medical Journal*, Feb. 18, 1897, is an interesting article upon slowly absorbable antiseptic catgut, prepared by a modification of Boeckmann's method, by C. W. Borden, M.D., U. S. Army. He believes that the chief merit of the method is in rendering the suture material much more slowly absorbable by boiling it for an hour and a half in a 1/500 solution of mercuric bichlorid in alcohol. This antiseptic catgut has given, in his experience, most excellent results. He does not think the small amount

of bichlorid of importance in producing irritation or wound secretion, and that it is readily disposed of in the tissues without injury. He believes there is as little danger of bichlorid irritation as of iodoform poisoning from using the formalized catgut soaked in an alcoholic solution of iodoform, recommended by Senn.

Dr. Borden thinks that it is of manifest advantage to add his method of making an antiseptic suture to that of Boeckmann, which consists in sterilization by dry heat. He considers that the formalin method of Hofmeister produces a catgut not in any way equal to that which he recommends. He thinks kangaroo tendon has been greatly overrated and attempts to show by an experimental study of a wound that it is far less resistant to the tissues than has been usually considered, and singularly believes it conclusive by giving a photograph of a frayed end of a kangaroo tendon suture emerging from the skin, "where it had been completely eaten through by leucocytes." Such examination teaches only the extraordinary rapidity with which the active proliferating processes supervene in the superficial layer of the skin, and this phenomenon has often been remarked upon in contradistinction to the processes which take place when the suture is buried in the tissues. The same process is observed uniformly, when the sutures are deeply taken through the mucous surfaces, as for example, the continuous over-and-over suture taken through the cervix of the uterus. Dr. Borden has taken the trouble to reproduce by micro-photographs the difference which followed the implantation of "unbichlorid kangaroo tendon and bichlorid catgut" in a septic wound, and shows that the tendon is less irritant than the catgut to disintegration changes. This should follow, if the bichlorid is of any value in preventing decomposition. He reports no attempt to show results where the catgut and kangaroo tendon, both of good quality and sterilized by the same method, have been aseptically buried in the same animal. Here, as I long since demonstrated, the contrast is most marked, and the results show that the tendon remains comparatively unchanged for a much longer period.

In the coaptation of the skin the subcuticular suture should be completely buried. The first end is fastened by a half knot, after the skin is penetrated. The stitch is taken parallel to the long axis of the wound, each succeeding stitch entering exactly opposite to the emergence of the previous one, and secured where the needle finally emerges through the skin by a half knot as at the beginning. This holds the edges in even, close coaptation. The ends of the suture are cut even with the skin, and slight tension in the long axis of the wound causes the ends to disappear below the surface (buried). It is then sealed with iodoform contractile collodion without drainage. The skin suture should be a fine one, and it is important to implant it only in the deeper layer of the skin, subcuticular; otherwise the skin may proliferate before absorption ensues and superficial abscesses follow.

Sterilization of tendon. A small portion of the dried tendon is soaked for a considerable period in a warm solution of bichlorid of mercury (1-1000). When well softened the tendons are easily separable. Each individual tendon is laid straight upon a wet sublimated towel and allowed to dry. When dry they are assorted. In this state they may be used with comparative safety. I have never been able to

cultivate bacteria where culture tests have been made of tendons thus prepared. By reason of its histologic structure, as before explained, the tendon, when buried in the tissues, is much more slowly penetrated by the proliferative leucocytes than catgut. The effect of chromic acid upon the intercellular cement substance is extraordinary. It fixes it by a process of tanning and does not in any way interfere with its pliability, increases somewhat its tensile strength; causes it to absorb moisture more slowly and renders it much more resistant to the disintegrating influences, when buried in vitalized structures.

The tanning of certain grades of leather has been much improved by a somewhat similar use of chromic acid. The process is not only much shortened and cheapened, but the resultant product is very much more valuable. Recently, a large manufacturer showed me a goat skin thus tanned. It was not fine leather, but he said it would make a durable shoe, whereas under the old processes of tanning it would hardly be worth manufacturing. These methods are protected by patents and have already earned the owners over two millions of dollars. Chromic acid may be applied to the suture material in a strength which renders it unfit for use and makes it almost as slowly absorbable as silkworm gut. When properly chromicized, the suture should be of a light golden color and slightly translucent. It may be well preserved for an indefinite period in the dry state, but, as Lord Lister long ago pointed out, preserved in light-colored boiled linseed oil, to which 5 per cent. of carbolic acid has been added, it seems to keep indefinitely, and for a certain period, I think, is improved by age. When only partially immersed, as in a bottle half full of oil, the tendon becomes sticky and is greatly damaged. If replaced, after being removed, in a wet state, in the carbolized oil, the water in the tendon forms a sort of emulsion which speedily ruins it. It may be preserved in many of the different ways which have been recommended for catgut, and so far as I am aware I have tried them all. By none, however, has the product remained permanently as reliable as by the method just given. Kangaroo tendon prepared as above is objected to because of the trouble in preparation and its cost; trouble in that the oily product is difficult to seal after having been bottled, and the oil must be removed from the tendon before using. However, the latter is easily effected by immersing the sutures, just previous to use, in a warm sublimate solution for half an hour. I consider the antiseptic quality resulting from the remaining bichlorid beneficial rather than otherwise.

Is such tendon trustworthy and assuredly aseptic? Infective wounds, from a variety of causes, will follow in a small percentage of cases in the practice of every surgeon, but it is his imperative duty to exercise every possible care to prevent it. The sterilization by heat is considered absolute, hence instruments, towels, gauze, etc., may be assumed non-infective. The certainty of such knowledge, so far as suture material goes, is of equal importance, and hence the oft-repeated injunction, "trust no sutures that you have not personally prepared." By culture tests I have assured myself that the tendon is sterile and each of the various processes in its preparation is always conducted under my personal supervision. The query most often made is "What shall I do with the unused tendon that has been soaked in the bichlorid solution?" Wrapped in a sterilized towel, it should be

sun-dried, and when thoroughly dry, replaced it in the carbolic oil for future use. Repeated treatment in this way leaves the tendon undamaged. For the last two years I have soaked the tendon for a considerable period in a solution of formalin, prior to its chromicization. This is a still further guarantee of disinfection.

Boiling in alcohol has been a favorite method with many surgeons for the disinfection of catgut. Sterilization of tendon may be effected by this method, but it renders it brittle, hard, and is much less satisfactory in its application. Dry heat is less damaging than by any other, except the above-mentioned chemical processes, and leaves a product more satisfactory than when boiled in alcohol. It is also perfectly easy of application by the simplest of all methods. There are two requisites, however, which are essential, the tendon must be entirely freed of the *oil* and *moisture*. A simple means of drying is to retain it for some hours in the sunshine, or in a warm oven. A coil of the dry tendon is placed in a large test-tube, with a dry cotton plug; over the end of the tube a rubber cap is securely tied. This is put in the sterilizer as long as it may be deemed desirable and thereby is known to be trustworthy. If only a very slight degree of moisture remains in the tendon, the resultant will be a compact mass of ruined material.

Tendon will bear repeated heating in this way with comparatively little damage, and it may be recommended as a safe means of assurance to the surgeon that any possible subsequent infection of the wound is not caused by his suture material. Kangaroo tendon sutures should be obtained at a cost of ten dollars per hundred, and so great has been the demand for it that I have had it prepared in quantity, under my personal supervision, for general use, which I fully believe is absolutely trustworthy and reliable. These sutures are coming into general use. I am constantly in receipt of letters reporting the great satisfaction following their employment; I have already quoted Dr. Coley. Dr. F. W. Longyear of Detroit says: "My experience has been entirely with this material, and has extended over a period of more than four and one-half years, during which time I have used it for both ligature and suture in fifty-seven cases of celiotomy, with and without drainage, and I have yet to see my first case of post-operative hernia where this material was employed."

Kangaroo tendon ligatures, ten or twelve inches in length, should cost less, since in the preparation of sutures which are long, fine, smooth and even, the larger part of the gross material is rejected.

It is quite difficult to obtain really fine sutures, and much placed upon the market is not of first quality. I have written the above description in careful detail, since there can be no question but that the use of the buried animal suture marks the greatest advance in the development of aseptic surgery. When applied in closing the abdominal wound by suturing the different layers independently, the skin also closed by a subcuticular continuous suture and the wound sealed with iodoform collodion, hernia is practically avoided. In over eight hundred aseptic laparotomies thus closed I have had but once subsequent hernia, and that in an extremely thin abdominal wall after the removal of a large uterine myoma. The cure of hernia by any of the so-called modern methods is dependent absolutely upon the use of buried sutures in closing the neck of the sac, reinforcing the weakened struc-

tures and the reconstruction of the obliquity of the inguinal canal, and it was for this very purpose I first employed animal sutures in 1870. With all the emphasis of an earnest conviction, I commend to every aseptic surgeon familiarization with the methods of wound closure by means of buried absorbable sutures, preferably tendon, and not alone predict their general adoption, but believe that in importance they hold the first place in the technic of modern aseptic wound treatment.

THE THERAPEUTICS AND SURGERY OF THE CEREBRO-SPINAL AXIS.

Presented to the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY SAMUEL KNOX CRAWFORD, M.D., LL.D.

CHICAGO, ILL.

It is safe to assert that the cerebro-spinal axis is the master-wheel for man's animal machinery. If the mainspring of a watch becomes interrupted in its integrity, the gearing throughout the entire structure becomes disturbed, its functions as a chronometer cease, and it stops. If the drivewheel of a locomotive engine be impaired, the functional activity of the great iron drudge is interfered with, and the creature must rest and be repaired before activity in function can be regained. If the centerpiece of the complicated machinery of a large manufactory becomes deficient or inoperative, the whole concern must shut down for repairs at any cost. In consequence of the dangers besetting mainsprings, drivewheels and centerpieces, extra protective measures are adopted for their continuous functional activity and uninterrupted security. In most cases an alternate or duplicate is provided that functioning may be assured.

The careful student of this piece of workmanship will have observed early in his work that the law of protection and compensation has been strictly obeyed by encasing the central nervous system in the cranial and spinal cavities in two symmetric halves, the one incasement in bony pieces, enduringly immovable; the other in irregular blocks endowed with enduring possibilities, all lined with tough and resisting fibrous membrane of remarkable endurance, closely adherent to the inner surface of the bones and outer walls of cavities, and for the most part furnishing protective sheaths to the outgoing nerve trunks—adherence most marked where dangers are most threatened at the sutures within the skull, but secure throughout the entire extent of both cavities. This is familiarly known to anatomists as the dura mater, from its enduring qualities. Immediately surrounding the medullary mass and intimately investing it, is a delicate membrane composed of vascular netting, threads of which, large and small, penetrate the mass and form plexuses on the walls of the cavity within. This webbing of blood-vessels becomes plainly the nutrient mother of the system, and is hence called pia mater. Between the two maters hangs another membrane, delicate in its fibrous structure and somewhat adherent to both. Its suspensory, lubricating and protective functions are plainly in evidence. This is the arachnoid membrane, and it serves in a triple capacity.

Epitomized, the membranous structures of the axis may properly be stated to be: the dura mater, for protection; the arachnoid, for suspension and the accommodation of movement, and the pia mater, for the

accomplishment of the essential act of life—its nutrition.

Between the maters is the arachnoidian space and membrane with communication throughout the entire extent of the axis. Another fact may be stated without argument. The cerebro-spinal axis is a hollow organ itself from end to end, and the vascular netting passes through and forms an anastomosis on the walls of the lumen. Schiff, Quinke, Leightheim, Fucrbinger and others have clearly demonstrated that lumbar puncture can be practiced with more or less impunity, and that, as a diagnostic measure, the operation is of great value, enabling the diagnostician to locate with accuracy the approximate position of certain pathologic processes in meningeal affections. The admitted impunity with which the procedure may be accomplished lends assurance of safety in establishing permanent fistule in the lumbar, dorsal, cervical, or even in the cranial regions, as is done in the various abdominal localities for establishment of artificial anus, so efficient in many surgical measures for the relief of disorders of the intestines. Because of the dangers from infection by perverted natural discharges from the intestines, the abdomen would be the more critical field to invade.

No more vitalizing agent has been created than oxygen, and no more active and unerring antiseptic agency has been, or ever will be, devised than ozone, which is electrically condensed oxygen. In all diseases of the central nervous system the first indication is to remove the inevitable pressure, whether from the effusion of blood or of serum or from bony environment, either from deformity or depressed bony spiculæ of traumatism, infection or vitiated nutrition.

The next move in the process of therapeutic procedure is to correct by every means at command this disturbed nutrition, which is constantly in evidence in all morbid processes. Direct medication is the modern advance in therapeutic procedures as illustrated in antiseptics. Through a permanent fistulous opening at any point throughout the extent of the cerebro-spinal axis may be injected safely and with facility, a stream of oxygen or ozone into the interior of the mass, and therefore brought to bear directly on the plexuses, and thence into as intimate relation with the floating column of corpuscles as in the air cells of the lungs, and doubtless with the same vitalizing effect, or the gaseous current may be directed into the arachnoidian space and thus be brought to bear in the same way and with equal efficiency on the vascular structure of the pia mater.

With a tissue as highly endowed with facilities for a constant supply of nutritive fluid as in the central nervous system, and charged with the all-important functions in evidence in it, a theory consigning it to be hopeless destruction and irretrievable ruin on every occasion when circumstances of traumatism or infection present is phenomenally absurd. Any part of the cerebro-spinal axis whose special function may be suspended for a sufficient length of time to afford rest and opportunity for a correction of interrupted nutrition may be safely invaded by the surgeon's knife, and repair as confidently expected as from mutilations in any other part of the body, with liberal margins in favor of the nerve mass and the bones entering into its encasements.

At the beginning of a great war with a foreign foe, whose chief historical characteristic is cruelty, and shaking from our national policies the isolations and

conservatism of the past to become aggressively civilizing, if not, indeed, cosmopolitan or imperial, with all that these new national movements involve, I appeal to the science of surgery and the brilliant array of American operators on behalf of the human brain, the central nervous system, or the cerebro-spinal axis. I make this appeal the more earnestly, knowing as I do, that thousands of the flower and promise of our manhood must fall before the foes upon whom we must move in the sacred cause of humanity.

Modern warfare inflicts ten wounds about the head and face to one below the waist. The field for operative procedure and therapeutic study for the military surgeon is above the waist in large degree, and in this the head and face prevail over all others, and the reasons for this are plain, when we consider the manner of offense and defense. The military surgeon of today has opportunity long and wide for making himself an important factor in the march of the world in behalf of civilization and in the interests of humanity.

AN INQUIRY INTO THE NORMAL ANGLE OF JUNCTION OF THE NECK, WITH THE SHAFT OF THE FEMUR.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY M. H. SEARS, M.D.

PROFESSOR OF DESCRIPTIVE ANATOMY COLORADO COLLEGE OF DENTAL SURGERY AND LATE ADJUNCT ANATOMIST OF MEDICAL DEPARTMENT UNIVERSITY OF COLORADO, DENVER, COLO.

In the examination of this subject, an effort has been made to confine the inquiry to specimens of the male bone fully developed, free from the results of injury or disease, and ranging in age as nearly as could be determined from twenty-five to forty years.

These extremes of age are selected arbitrarily, for between these periods of life the bone may be said to be at the height of its development—it has neither the deficiencies of incomplete growth or the defects of degeneration incident to age; it may be presumed therefore to be typical in all of its detail. As is well known, two angles are formed by the neck of the femur with the shaft of the bone, the upper being an acute angle, while the lower is an obtuse angle and gentle curve from the lower portions of the neck to the internal border of the shaft with which it becomes continuous. The arrangement of the bony fiber of the neck and the position of the neck itself upon the shaft is undoubtedly for minimizing the strain of the bodily weight above, in its transmission to the upper extremity of the bone below. These facts are now generally well recognized. It will also not have escaped the notice of the observer that the trochanter minor acts as an additional and powerful support to the neck of the femur upon its posterior and internal aspects, assisting greatly in transmitting the bodily weight. Again the perpendicular diameter of the base of the neck is greatly increased, as compared with the transverse measurements of the bone at the same place, also for the natural purpose, quite evidently of compensating for the change in direction of the strain of the bodily weight by increased strength and quantity of bony structure, the change in direction being from a perpendicular line to an angular line passing from the cup-shaped cotyloid cavity to

the globe-shaped hemispherical upper extremity of the femur.

These circumstances, different in minor degree in different individuals, alter the angle of junction at the neck with the shaft somewhat, but in a way that makes it quite evident that there is a maximum and minimum degree of angularity between which extremes the angle of junction presented by any given specimen of the bone may be said to be normal.

In order to arrive at conclusions worthy of credence some definite method of anatomic measurement dependent upon fixed anatomic relations should be devised. When these relations varied in any given specimen of the bone which I examined, it was noticed that the angle of junction also varied in a like proportional degree, but always within the extremes of angularity above alluded to as probably being normal. In selecting specimens of the bone from which measurements were made for the purposes of this paper; those bones were chosen which presented on the anterior surface a large venous foramen—usually much larger than its neighbors—which was placed immediately below the spiral line and in a position which seemed to be the anatomic center of the shaft. Through this opening a perpendicular line was projected, which was also parallel to the axis of the shaft as nearly as could be determined. The position of the foramen in the specimens selected seemed also to be placed about one-sixth of an inch below the anatomic center of the neck of the bone, for the reason that a line projected through the center of the neck and representing its axis—as nearly as could be determined—intersected the line of the axis of the shaft at one-sixth of an inch above the foramen, thus establishing perhaps the true angles by which a bone should be measured. The two angles established are an upper acute and a lower obtuse angle. After establishing these angles and marking them upon the several bones examined by use of ink, they were carefully examined and measured with an angleometer, an instrument of precision for exact measurements of this character. In some twenty-five or thirty specimens examined—a number not sufficient to establish fixed rules, however—the minimum acute angle measured was 38 degrees, while the maximum acute angle was 52 degrees, the average angle being 47 degrees and 30 minutes, there being a few minutes less or additional as the case might be in many of the bones examined. When the place of the foramen varied from the position of one-sixth of an inch below the spiral line, but still maintained what seemed to be the anatomic centers of the neck and shaft with reference to that line, it was noticed that the acuity of the angle became less, thus if the foramen was placed at one-fifth or one-fourth of an inch below the line, the acuity of the lesser angle approached the minimum angle of 38 degrees, which has been named as the minimum angle noticed in this series of specimens. It is, of course, unnecessary to remark that the greater or obtuse angle is to be found by subtracting the measurements of the acute angle from the measurement of the axis of the shaft of the femur, which was assumed to be 180 degrees.

As is indicated by the title of this brief paper, its purpose is to record merely the results of an inquiry. The method adopted to attain these results is offered to the Section upon its merit for what it is worth.

McPhee Building, Denver, Colo.

THE TREATMENT OF INOPERABLE SARCOMA WITH THE MIXED TOXINS OF ERYSIPELAS AND BACILLUS PRODIGIOSUS.

IMMEDIATE AND FINAL RESULTS IN ONE HUNDRED AND FORTY CASES.

Presented to the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY WILLIAM B. COLEY, M.D.

ATTENDING SURGEON TO THE NEW YORK CANCER HOSPITAL; ASSISTANT SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED. NEW YORK, N. Y.

Three years ago, at a meeting of this body in Baltimore, a paper was read upon a similar subject by a distinguished surgeon. In that paper, based upon a personal experience of nine cases, three of which were carcinoma and a large proportion of the remainder types of sarcoma, which I had myself regarded as unfavorable, the broad generalization was made that the method was of no value, and the prophecy was ventured that in one year from that date it would be forgotten and buried in that oblivion that has furnished a quiet resting-place for so many of the brilliant cancer cures that have from time to time dotted the medical history of the past.

In the discussion of the paper I was rash enough to dissent from these conclusions, and in spite of the warnings and criticisms of the skeptics, I have steadily persevered along the same lines, and am here today to present the results of my work, leaving you to be the judges whether or not my labors have been in vain.

I have felt that the question was one that depended for its solution, not upon high authority or *a priori* arguments, but rather upon facts, derived from careful observation and large clinical experience. At that time I had treated eighty-four cases of inoperable malignant tumors with the mixed toxins; and no one could possibly have witnessed as I had, a considerable number of cases of hopelessly far advanced inoperable sarcoma, the diagnosis of which had been confirmed by the most skilled pathologists, entirely disappear under the injections of the mixed toxins, without being convinced that there was *something* of value in these toxins. It seemed to me that these successful cases, some of which at that time had remained well nearly three years, more than offset the many failures I myself as well as others had had. Moreover, it seemed reasonable to suppose that further investigation would enable us to improve the method as well as to ascertain just what types of tumor were most influenced by the toxins. Time will permit but a hasty review of the earlier cases already reported (*Am. Journal of Medical Sciences*, September, 1896), yet some review is of the utmost importance, since it is only by a study of the older cases that we are able to determine the permanence of the cure. With this end in view I have tabulated all of my cases of sarcoma, giving the final results as far as ascertainable.

I have decided in the present paper to confine my remarks almost entirely to sarcoma, and I have so decided for two reasons. The first and chief reason is to correct, if possible, the misunderstanding that I have found so common among men who have read the subject but casually, viz.: that the toxins are advised indiscriminately in all cases of inoperable cancer, whether sarcoma or carcinoma. Some excuse for this mistake may possibly be found in the titles of my

former papers, yet a careful reading of the papers themselves, and especially the conclusions, will show that I have advised the toxins practically only in sarcoma and have stated that their use in carcinoma was, up to the time in question, largely experimental. I did state that I believed good results, similar to those obtained in sarcoma, would in time be obtained in carcinoma. While that time has not yet come, I can claim, I think, some reason for my belief in a few cases of carcinomatous nature attended with marked results. However, until this number has considerably increased, I think it wise to restrict the toxins to sarcoma, and it is needless to say, to inoperable sarcoma. I have never advised the treatment in cases of sarcomas amenable to operation, unless it be in a few cases where a brief period of treatment was advised with the idea of avoiding amputation of a limb. If the tumor be in the soft parts, and especially if spindle-celled, I believe it justifiable and even strongly to be advised to try to save the limb. I have now a patient who has been well nearly two and one-half years with rapidly recurrent spindle-celled sarcoma of the right hand, in which amputation of the arm would have been done had not the growth disappeared under the injections. I do not consider her cured, and shall not until she has gone beyond three years. Dr. L. L. McArthur of St. Luke's Hospital, Chicago, has had a case of recurrent spindle-celled sarcoma of the leg and a three times recurrent sarcoma of forearm, which disappeared under the toxins and made amputation unnecessary. Dr. John E. Owens of Chicago has also had a similar result in a case of round-celled myeloid sarcoma of tibia. All of these cases are well three years after treatment, and in three the diagnosis was confirmed by microscopic examination. I do not believe the chances of a cure by amputation are jeopardized by the short time necessary to determine the success or failure of the toxins. In cases of rapidly growing, small, round-celled sarcoma of the bone I would not advise the toxins, but immediate amputation. I have used the toxins in a few cases after primary operation as a prophylactic measure to lessen the chances of recurrence. Theoretically, this use of the toxins has much to recommend it, but my cases are as yet too few in number to warrant me in making any positive statements as to its value.

Method of preparing the toxins and technic of administration.—The preparation I have used the past three years is the same as described in my last paper, viz.: the mixed, unfiltered toxins of the streptococcus of erysipelas and the bacillus prodigiosus, made from cultures grown together in the same bouillon and sterilized by heating to 58 degrees C.; in children and patients much reduced in strength I have used the filtered toxins prepared by passing the mixed living cultures through a porcelain filter. This preparation is much weaker than the unfiltered, the relative strength of the two being about 1:10 or 15. The effect of the filtered solution upon the tumor is less marked than that produced by the unfiltered. The toxins used during the last five years have been prepared by Dr. B. H. Buxton of the Loomis Laboratory, New York. In the earlier cases the toxins were made from cultures of streptococcus of erysipelas obtained from a fatal case, but during the last three years a sufficiently high degree of virulence has been obtained by frequently passing the cultures through rabbits. Some of these cultures that had been passed through upward of sixty rabbits were experimented

with by Drs. W. H. Park and Alexander Lambert of the Board of Health Laboratory, and it was found that 1 c.c. of a bouillon culture reduced to one millionth part of its strength by dilution, was capable of killing a rabbit within twenty-four hours. This increase in virulence has been, I am convinced, a direct factor in the success of the toxins, and in fact, it was to increase the virulence of the erysipelas cultures that, in 1892, I first combined the bacillus prodigiosus with the streptococcus of erysipelas, Roger of Paris having proved that the latter germ had the power of making the streptococcus more virulent in rabbits, though as far as I know, it had never been used in the human body, nor had the combination ever been suggested in connection with the treatment of malignant tumors. I have never claimed to be the first to suggest the idea of substituting the toxins of erysipelas for the living cultures. Lassar of Berlin was, I think, the first to do this, in 1891, and Spronck of Utrecht, in October, 1892 (*Annals de l'Institut Pasteur*), reported twenty-six cases of carcinoma and sarcoma treated with a preparation of toxins of erysipelas prepared in the same way as Koch's tuberculin, but neither observer obtained a single complete success. Previous to Spronck's paper I had experimented with bouillon cultures of erysipelas heated to 100 degrees C., having been led to this by the marked improvement I had observed to follow repeated injections of living cultures, even when no erysipelas was produced. Dec. 12, 1892, I presented to the Surgical Section of the Academy of Medicine the results of repeated injections of living bouillon cultures of the streptococcus of erysipelas in ten cases of inoperable malignant tumors, and in this paper I stated that "In view of these results (my own), as well as those of Spronck, it may be considered definitely proven that a portion, if not all, of the benign influence of the toxins of erysipelas, rests in the toxic products rather than in the germ itself. The fact that thus far the results from an attack of erysipelas have been by far more brilliant and permanent, proves that either the germ itself or its continued action plays an important rôle, or, what is quite as probable, we have not yet learned how best to isolate the toxic principles and to use them in the most efficacious doses."

However much difference of opinion there may be as to the part the bacillus prodigiosus plays in causing the disappearance of sarcoma, and I am conscious that some claim it has no value at all, the fact remains that all of my own successes, as well as those of other surgeons, have been obtained with the combined toxins, and as far as I know, no one has recorded a successful case treated with the erysipelas toxins alone.

I have experimented in a large number of cases with the erysipelas toxins, at first alone, and later in combination with the bacillus prodigiosus, and I am quite convinced that the process of degeneration of tumor tissue is greatly increased by the prodigiosus toxin. Many opinions have been expressed as to the nature of this process, by means of which a cure is effected in the successful cases. The opinion which has been most generally advanced, though usually resting on theoretical, rather than practical knowledge, is that it is a simple necrosis or sloughing process resembling that following the injection of any powerful escharotic like carbolic acid; consequently it has been regarded as an entirely local process. Nothing could be farther from the truth. While in some cases of

soft, round-celled sarcoma the rapid breaking down of the tumor would lend support to this view, there are many cases that absolutely disapprove its correctness. A number of cases of sarcoma have disappeared entirely by absorption with no breaking down, and furthermore, in several the injections were made remote from the tumor. This proves the action to be systemic as well as local. The toxins in some way, probably acting through the blood serum, cause a coagulation necrosis with fatty degeneration of tumor cells, the breaking down and formation of a slough depending entirely upon the preponderance of the cellular elements over the intercellular or fibrous stroma. In the spindle-celled variety, absorption without breaking down is the more common, while in the round-celled type, the reverse is true. Usually, when possible, I prefer to give the injections locally, for I have found the effect more rapid and more marked than when given subcutaneously and remote from the tumor. A much larger quantity can be safely given subcutaneously than when injected into the tumor, and this is a point of great practical importance. I have seen a severe chill and a temperature of 105½ follow the injection of one minim of the mixed unfiltered into a vascular sarcoma, when ten minims subcutaneously would have caused less reaction. In other words, the severity of the reaction depends largely upon the rapidity of absorption.

Dosage.—The rule should be to begin with a minimum dose and slowly increase each day until the desired reaction has been obtained. If this rule is carefully observed I believe the element of danger to be exceedingly small. It is evident that the dose depends largely upon the virulence of the cultures, and since it is extremely difficult to keep cultures of the same virulence the dose must vary within certain limits, and must be determined in the individual case by trial, the thermometer furnishing the guide. During the past two years the strength has been very uniform. Toxins produced from very virulent cultures, such as I am now using, mixed, unfiltered, should never be given in larger initial doses than one-half minim or 0.32 c.c. Boiled water may be added to each dose to obtain the proper dilution. Each day the dose should be increased by one-half minim until the reaction temperature reaches 102 degrees or 103 degrees. The toxins may be used undiluted in doses of one minim or more, as this quantity can be carefully estimated with a well-constructed hypodermic syringe. If the injections are given subcutaneously, remote from the tumor, larger doses are borne, and in that case one minim can be given as the initial dose, and increased one minim daily. The amount required to produce a chill and temperature of 102 degrees or 103 degrees, varies with the individual case; one to two minims injected into the tumor will generally be sufficient. If the reaction is severe, the chill usually occurs within fifteen to twenty minutes of the injection. If the temperature following chill reaches 104 or 105 degrees, which is higher than one should aim to obtain, some stimulation with whisky and strychnin may be indicated. Nausea and vomiting usually occur in the severe reactions, but they are of short duration, and after one or two hours the temperature begins to fall and should reach normal within twelve hours. Following small doses, headache, slight muscular pains, especially in back, and a feeling of general malaise are the only symptoms observed, and these soon pass. It is unnecessary to

produce a chill after every injection; in fact, some of my successful cases had no more than four to five chills during the whole course of treatment. The aim should be not to cause too much depression, for in that case the patient is unable, for some time, to stand even small doses. Many of the successful cases steadily gained weight during the treatment, which disproves the statement of some writers that the treatment is exceedingly depressing and causes rapid emaciation. This may be true if the doses are too large, but not when the method is judiciously carried out. Strychnin may cause speedy death or act as an excellent tonic, according to the dose administered.

Aseptic precautions.—Inasmuch as the administration of these as well as other toxins undoubtedly increases the liability to infection if pathogenic germs are present, too great caution can not be exercised in sterilizing the hypodermic needle and the skin. If a tumor be ulcerated or broken down, great efforts should be made to keep the parts aseptic. Lack of such precautions has certainly been the cause of death in a number of the fatal cases.

Duration of treatment.—Fortunately it is possible in most cases to tell in a comparatively short time whether or not the toxins are likely to be effective. If no beneficial results are apparent after three weeks' treatment, I believe it useless to continue the injections. In nearly all of my successful cases marked improvement was seen within a week after the first injection, though final cure required, in some cases, several months of treatment. In one case, one of inoperable spindle-celled sarcoma of the abdominal wall, the tumor entirely disappeared under thirty injections and the patient is now well, one and one-half years later. The question of danger of long-continued injections of the toxins is an important one. One patient with thrice recurrent rapidly growing carcinoma of breast and axilla had the toxins steadily for two and one-half years. The doses were moderate, seldom producing a chill, and averaged two a week. The tumor has disappeared. The patient gained ten pounds in weight and her general health was perfect. The tumor finally recurred, ran a rapid course, causing death in six months.

Another case, an eight-times recurrent spindle-celled sarcoma of the chest wall (soft parts), has had the toxins with occasional intervals of rest for nearly four years. The disease has been kept almost completely in check by small doses of the filtered toxins and the treatment has not interfered with the duties of the patient, who is a well-known physician.

Macroscopic changes in the tumor.—The changes in the tumor that are first detected are: marked decrease in vascularity, loss of the smooth, glossy appearance of the overlying skin and later the presence of small wrinkles in the skin; the tumor soon becomes much more mobile and loosely attached. Marked decrease in size is often noticed within three or four days after treatment. Cessation of pain is in many cases caused by the treatment and anodynes which, though indispensable, before are no longer needed.

REVIEW OF IMPORTANT CASES ALREADY REPORTED, WITH SUBSEQUENT HISTORY.

Case 1.—Recurrent inoperable spindle-celled sarcoma of neck and tonsil, treated with injections of living cultures of erysipelas for four months. Well six years. Although this case was treated with repeated injections of living bouillon cultures of erysipelas and not the toxins the result was so remarkable that I may be pardoned for referring to it. The tumors nearly dis-

appeared and the patient recovered his general health; well May 1897, six years later.

Case 2. Recurrent sarcoma of back and groin, mixed-celled, round, oval and spindle. Male, aged 40. First treated on April, 1892, with repeated injections of living bouillon cultures of erysipelas. Entire disappearance; rapid recurrence two months later, final disappearance under the mixed toxins. Four more attacks of erysipelas artificially produced, and with less effect, in January 1893. The patient remained well three and one-fourth years, and in September, 1896, had an intra-abdominal recurrence in the retroperitoneal region. The tumor increased rapidly in size. In November, 1896, the patient became markedly jaundiced, but at the end of six weeks the jaundice disappeared and did not return. He gradually failed and died in April, 1897. Autopsy showed a large, hard tumor starting behind the posterior parietal peritoneum, pressing the viscera forward against the abdominal wall. The pathologic report of the original tumor made by Dr. Farquhar Ferguson of the New York Hospital was given in full in my last paper. It was a mixed-celled sarcoma, round, oval and spindle-celled.

Case 3.—Inoperable spindle-celled sarcoma of the abdominal wall and pelvis. Entire disappearance of the tumor under four months' treatment with the mixed filtered toxins; well at present, five years later. Patient male, aged 16, years, admitted to the New York Cancer Hospital in January, 1893, having been referred to me by Dr. L. Bolton Bangs as a totally inoperable sarcoma, the diagnosis having been confirmed by microscopic examination by Dr. H. T. Brooks, pathologist at the Post-Graduate Hospital. The entire tumor, 7 x 5 inches, completely disappeared and at my last examination made, May, 1898, the boy was in perfect health, free from recurrence, upward of five years.

Case 4.—Inoperable sarcoma of the abdominal wall. Entire disappearance under two and one-half months' treatment with the mixed toxins (filtered and unfiltered.) Patient is perfectly healthy at present, three and one-half years after treatment. The patient, a woman, aged 28 years, had had an exploratory laparotomy performed in August, 1893, at the Massachusetts General Hospital, by Dr. Maurice H. Richardson. A tumor was found involving such a large portion of the abdominal wall that removal was impossible; a portion was excised and pronounced spindle-celled sarcoma by the hospital pathologist, Dr. W. F. Whitney. She was referred to me in October, 1893, by Dr. Richardson. June 1, 1898, she was in perfect health with no sign of induration at the site of the tumor.

Case 5.—Spindle-celled sarcoma of the leg and popliteal region, three times recurrent; disappearance under the toxins; recurrence in the gluteal region after one and one-half years. Female aged 16 years. Further treatment with the toxins caused decrease in the size of the tumor until it was possible to remove it by operation. One year later signs of returning growth appeared in the popliteal space as well as in the stump of the leg. Amputation at the middle of the thigh was performed. Since the amputation the patient has been given injections from time to time with the filtered toxins with the idea of preventing a further recurrence. She is at present in good health, June 1, 1898.

Case 6.—Spindle-celled sarcoma of the scapula involving large part of left half of the thoracic wall. Entire disappearance of the tumor under three months treatment with the mixed unfiltered toxins; patient in perfect health, without recurrence, Jan. 22, 1898, four years later. As this is one of the most striking cases of success with the toxins, a brief abstract of the history will be given: The patient, a girl aged 16 years, was admitted to the New York Cancer Hospital June 20, 1894. The tumor had started in the left scapular region, four months before, and had grown very rapidly until the time of admission; the tumor measured 13 inches vertically behind and extended around beneath the axilla and to the sternum in front. The growth was fixed to the scapula and to the ribs, and probably originated in the soft parts over the scapula; it was about two inches in thickness in its most protuberant part, the skin over it being normal and perfectly movable. The left arm was bound down by the new growth so that it could scarcely be raised to a horizontal position. The mixed, unfiltered toxins were injected locally into the scapular portion of the tumor and continued with intervals of one to two days for nearly four months. Immediate and very striking improvement followed; at the end of three weeks the arm could be raised to a vertical position. After three months' treatment the tumor had entirely disappeared by absorption only, without breaking down. There was no evidence of inflammatory, tuberculous or specific disease. The diagnosis of spindle-celled sarcoma was moreover confirmed by careful microscopic examination by Dr. H. T. Brooks, pathologist to the Post-Graduate Hospital. This case was carefully examined by me June 23,

1898, and no evidence of return was found. General health perfect.

Case 7.—Intra-abdominal round-celled sarcoma, involving the omentum, colon and loop of small intestine and border of the liver. Exploratory laparotomy; diagnosis of round-celled sarcoma confirmed by microscopic examination by Dr. F. Schwyzer, pathologist to the German Hospital. This patient, a woman, aged 23 years, was operated upon by Dr. Willy Meyer at the German Hospital, August 16, 1894. Dr. Meyer stated that to remove the growth radically seemed impossible. He closed the abdominal wound and referred the patient to me for treatment with the mixed toxins. Treatment was begun in September, 1894; the injections were made sometimes into the abdomen, sometimes into the buttock. The treatment was kept up with occasional intervals until Feb. 7, 1895. The tumor mass which was distinctly felt at the time the treatment was begun, slowly decreased in size and June 25, 1896, no tumor could be felt. A sinus had persisted since Dr. Meyer's operation till March 4, 1896. Incision was made and the sinus traced into the gall bladder, and several calculi, one-half inch in diameter, tightly wedged in the cystic duct, were found; these were removed. The sinus still persists, but the condition of the patient when last seen, more than three years later, was that of perfect health.

Case 8.—Inoperable recurrent angiosarcoma of the breast, treated with erysipelas and prodigious serum, later by the mixed toxins. The patient, female, aged 59 years, had a three-times recurrent sarcoma of the left breast, of such size that operation was entirely out of question. She was admitted to the New York Cancer Hospital Jan. 20, 1895, and placed in the incurable ward. Physical examination showed a tumor occupying the region of the left breast extending from the anterior axillary line to the sternum, and from just below the clavicle nearly to the free border of the ribs; it was more or less fixed to the chest wall, and markedly protuberant. The patient's general condition was so bad that no attempt was made at first to give her the toxins; she was treated with small doses of erysipelas and prodigious serum, prepared by Dr. Buxton. The tumor slowly shrank in size and the patient's general condition improved; by September, 1895, the tumor had become so much reduced in size and was so loosely attached that it was easily excised under ether. Examination Jan. 30, 1896, showed the patient to be in good general condition with no evidence of recurrence. The diagnosis was confirmed by microscopic examination by Prof. T. M. Prudden of Columbia University, who pronounced it angiosarcoma round-celled.

Case 9.—Twice recurrent spindle-celled sarcoma of the palm of the hand; entire disappearance under two months' treatment. The patient, 20 years of age, had injured her right hand two years before. In July, 1895, a small swelling appeared in the palm of the right hand; in October, 1895, it had reached the size of a hickory nut and was removed. Speedy recurrence followed. A second operation was performed by Dr. Edward Martin of Philadelphia, on Jan. 2, 1896. Microscopic examination showed the tumor to be a spindle celled sarcoma. On Feb. 15, 1896, the patient was sent to me by Dr. Martin for trial with the toxins before resorting to amputation of the arm; the tumor had already recurred at that time at the site of the old cicatrix, $2\frac{1}{2}$ inches long and $1\frac{1}{2}$ inches wide; the mass was attached to the skin and firmly adherent to the tendons, but apparently did not involve the bony structures. The injections with the mixed toxins were begun on Feb. 15, 1896; the filtered preparation was used at first; later the unfiltered solution. The injections were made partly in the tumor itself, but the major portion were given subcutaneously in the arm. The treatment was given almost daily until March 30, when it was continued at her home by her brother, who is a physician. On May 15, 1896, the tumor had entirely disappeared and she was able to extend her fingers perfectly, 120 degrees having been the maximum extent to which she could straighten her fingers at the time the treatment was begun. She was presented to the New York Surgical Society for examination on May 27, 1896. The treatment with the filtered toxins has been kept up, with occasional intervals, to the present time, although in small doses, not sufficient to produce a chill. Not more than four chills were produced during the entire course of treatment. In October, 1896, there was a suspicion of glandular enlargement high up in the apex of the axilla. The patient was given ether, and a gland about the size of an olive was removed from the upper portion of the axilla near the clavicle. This gland was examined microscopically and was found to be distinctly sarcomatous, although it showed very marked degeneration. It may have been present when the treatment was begun, as it was very difficult to find it even at the time when removed. The patient at the present time, June 1, 1898, remains in perfect health. A slight thick-

ening was noticed in palm February, 1898. This has yielded to further use of the toxins administered chiefly in the arm.

Case 10.—Recurrent spindle-celled sarcoma of the thigh and groin, entire disappearance under the toxins. M. S., female, aged 48 years. Family history negative. Five years ago the patient slipped and strained the muscles of the left thigh; three years ago a lump appeared at the outer aspect of the left thigh about the junction of the middle and lower thirds. This grew slowly. March 7, 1896, operation at the New York Hospital by Dr. Wm. T. Bull. A tumor the size of a fist was removed; but the large mass in the inguinal region was not interfered with, inasmuch as it was impossible to remove the entire tumor in the thigh. There was much edema in the whole leg and thigh.

Pathologist's Report: Copy of the records of the New York Hospital Pathological Laboratory: "The material is a piece of skin and subcutaneous tissue and masses of voluntary muscular tissue. The skin is circular in outline and measures 10 cm. in diameter; there are two tumors alongside of each other; the one measures 5 cm. in diameter, the other $4\frac{1}{2} \times 3$ cm. In the deeper relations the lines of incision have gone very close if not through the tumor tissue. The larger tumor is soft and brittle and vascular; the smaller one is firm in consistency and whitish in color. Microscopically the structure of the tumor is that of spindle-celled sarcoma; the smaller tumor contains much more fibrous tissue."

The injections with the mixed, unfiltered toxins were begun at the New York Hospital, May 30, 1896, by Dr. Le Fetra, the house surgeon under my direction, and continued until June 15, every other day. Temperature reaction ranged between 101 and 103 degrees. There was a considerable diminution in the swelling; pain was less and the patient was able to walk upon the leg, which she could not do before. Examination June 16, 1896, shows a recent cicatrix, five inches long at the lower, outer aspect of the left thigh. The middle of the cicatrix, about one and one-half inch in width, had not entirely healed. In the region of cicatrix and to the outer side was an indurated mass, apparently the remains of the new growth. Measurement of the left leg four inches above the patella, was twenty-one inches. Right leg at the same point, sixteen inches. There was an ill-defined tumor in the left inguinal region; nothing could be felt in the pelvis. The swelling of the leg and thigh was much less than at the time of the injections were begun. The patient was admitted to the New York Cancer Hospital, and the injections were continued with occasional intervals of rest until September. At this time the tumor in the thigh and groin had entirely disappeared and the left leg had become normal in size.

Examination in January, 1897, showed no recurrence; measurement of the left leg the same as that of the right. In April, 1897, the left leg had begun to swell again and a small tumor was detected in the groin; induration of the old cicatrix also seemed slightly greater. The patient was again admitted to the New York Cancer Hospital, and the treatment resumed. At the end of three weeks the swelling of the leg has decreased considerably and the tumor in the groin has disappeared. The old cicatrix was removed and examined microscopically but no evidence of recurrence was found.

Case 11.—Spindle-celled sarcoma of iliac fossa, probably starting in the ilium. Mrs. D, aged 40 years, with a good family history in the early part of 1895 began to have sharp, stinging pains in the right iliac region. In May, 1895, she discovered a tumor in this region. This steadily increased in size, and on October 19, 1895, Dr. Johnston of Boston, performed an exploratory laparotomy. A tumor was found in the right iliac fossa about the size of a cocoa-nut, attached to the ilium as well as to the abdominal wall and totally inoperable. Its exact point of origin could not be made out, but from the exploration and subsequent examination I am convinced that it started from the inner portion of the crest of the ilium. A part of the tumor was excised and examined by Dr. William F. Whitney, pathologist to the Massachusetts General Hospital, who pronounced it "spindle-celled sarcoma." In November, 1895, the patient was treated with injections of the mixed unfiltered toxins (Buxton) by Dr. Farrar Cobb of Boston. In a letter Dr. Cobb states: "At the end of six weeks' treatment the growth has entirely disappeared."

On May 17, 1896, the patient came to me with a recurrence and entered the New York Cancer Hospital. Examination at that date showed a hard mass on the right side, extending from the crest of the ilium nearly to the level of the umbilicus and as far to the left as the median line. The tumor was apparently located in the ilium and abdominal wall. Her general health was excellent. The toxins were at once begun and continued with intervals of rest for three months. The outline of the tumor gradually receded toward the crest of the ilium, and

when she was discharged from the hospital the tumor was not more than one-fifth its original size when I commenced the treatment. She left with the understanding that she was to return in the fall and resume the injections. She was readmitted to the Hospital in November.

Examination showed the tumor to have increased considerably in size during the interval of rest, but on beginning the treatment the tumor at once began to shrink. Whenever the injections were made the patient noticed a peculiar burning feeling in the tumor, and this was true whether the injections were made into the abdominal wall or into the thigh. The abdominal wall was so thick with fat that few of the injections were made into the tumor itself. This patient was one of the very few I have seen in whom the toxins always produced very severe irritation in the skin. After each puncture a hard, indurated and very painful area the size of a half dollar would appear, and this would not pass away entirely for several days. When she left the hospital, June, 1897, the tumor had remarkably decreased in size. When last heard from, December, 1897, she was still in good health.

Case 12.—Inoperable sarcoma of the sacrum; entire disappearance; perfect health three years later.—The patient, male, aged 38 years, enjoyed good health until February, 1895, when he began to lose flesh and strength. He suffered severe pain in the lower part of the spine over the region of the sacrum, shooting down to the legs, more marked upon the right. On April 1, 1895, he consulted Dr. W. C. Deming of Westchester. At that time he was beginning to be lame in the right leg; soon after the lameness extended to the left leg as well. These symptoms progressively increased; pain was acute. On May 2 he was sent by Dr. Deming to St. Luke's Hospital. His normal weight of 175 pounds had decreased to 134 pounds. He was so lame that it took him one hour to walk a distance of half a mile. He was admitted to Dr. Francis P. Kinnicutt's service, who on careful examination of the rectum found a tumor attached to the anterior portion of the sacrum, the lower border of which could be reached with the index finger, but not the upper. The tumor was of firm consistence and apparently started in the sacrum. The patient was emaciated and cachectic; his general appearance was strongly suggestive of malignant disease. The diagnosis of Dr. Kinnicutt and the other physicians and surgeons who saw him in consultation was: Inoperable sarcoma.

On May 10, the very day I returned from the meeting of this Association at Baltimore, I found a letter asking me to see the case in consultation with Dr. Kinnicutt with reference to the toxin treatment. My diagnosis agreed with that of Dr. Kinnicutt, but owing to the weakened condition of the patient and the inaccessibility of the tumor, making it necessary to give the injections remote from the tumor, I gave a bad prognosis, although I deemed it advisable to give the patient the benefit of a trial with the toxins for two or three weeks, advising, if no improvement occurred in that time, to discontinue the injections. The injections with the mixed, unfiltered toxins were begun at once, and made into the gluteal region: the treatment was repeated daily and at the end of one week the pain had almost entirely subsided and the lameness had markedly improved. The treatment was carried out at St. Luke's Hospital for six weeks and at the end of this time the improvement was so great that the patient returned to his home in Westchester and resumed his work. The injections were continued by Dr. Deming two or three times a week in the evening, after the patient had returned from his work. By the end of June, seven weeks after the treatment had been begun, the patient had gained twenty-eight pounds in weight, and stated that he felt as well as ever. Examination in the early part of July showed a decided decrease in the size of the tumor, and his lameness had entirely disappeared. On March 8, 1896, I again examined the patient and found him in perfect physical health and weighing 175 pounds. On rectal examination I was unable to detect any trace of the tumor remaining. October, 1897, I again examined this patient and found him absolutely well, without a trace of recurrence. Present weight, 175 pounds. He has had no treatment since the fall of 1895.

The report of this case I owe to the courtesy of Drs. Kinnicutt and Deming, who had personal charge, although the treatment was begun by myself and carried out under my direction.

Case 13.—Inoperable sarcoma of the iliac fossa. E. S., male, aged 14; family history negative. History of injury: One and one-half years ago was dragged under a trolley car which caused some contusions about pelvis. In January, 1895, the patient began to feel a pain in the right groin. In February, 1897, he noticed pain in the right hip joint and groin which was at first thought to be rheumatism. He rapidly lost flesh and strength and the hip joint became less and less movable, and early in March, 1897, the attending physician, Dr. G. H.

Davis of Brooklyn, detected a tumor in the right iliac fossa, apparently starting from the ilium. The pain was exceedingly severe and constant. The tumor steadily increased in size and on March 27, 1897, he was taken to the Brooklyn Hospital and on March 29, exploratory laparotomy was performed by Dr. Geo. R. Fowler. A vascular tumor was found filling up the right iliac fossa, extending upwards about three inches above the crest of the ilium and Poupart's ligament. A diagnosis of sarcoma was made, and as it was clearly inoperable, the wound was closed and the parents were told that the case was entirely hopeless. The use of the erysipelas toxins was suggested as a last resort, but in view of the large size of the tumor and the weakened condition of the patient, little encouragement was given. The mixed, unfiltered toxins were begun in small doses on April 10, 1897. The injections were repeated daily with slowly increased doses; six minims were given before any decided reaction occurred. The injections were given in the gluteal region and not into the tumor. I first saw the patient in consultation with Dr. Davis on April 25, 1897. He had shown slight improvement since the injections were begun, but his condition at the time I saw him was so desperate that I gave a very bad prognosis. Physical examination at this time showed the patient extremely emaciated, with marked cachexia. His weight could not have been more than sixty pounds, his normal weight having been ninety pounds. The thigh was flexed on the abdomen to an angle of 120 degrees and motion was nearly absent; a hard tumor was felt in the right iliac fossa, extending upwards for about three inches above the crest of the ilium. The pulse was 130 and weak.

In spite of his apparently hopeless condition, I thought it wise for a short period to push the treatment to a point of obtaining marked reactions, and the dose was gradually increased up to 12 minims. At several times there was a well-marked chill with a temperature of 102-103 degrees following the injections. The improvement was immediate and rapid. I saw the patient again at the end of three weeks and to my astonishment found him walking about, able to straighten his leg and thigh completely. He had gained apparently no less than ten pounds and had a ravenous appetite. Examination of the abdomen showed that the tumor had almost entirely disappeared and now extended not more than a finger's breadth above Poupart's ligament. It is true that no microscopic examination was made by Dr. Fowler in this case, but the clinical history is so clear and striking that the diagnosis of sarcoma is scarcely open to reasonable doubt. The injections were not made into the tumor but into buttock and upper thigh. A few months later he developed a fluctuating swelling over the ilium behind. The skin became broken and slight infection occurred, causing some temperature. I incised the swelling, evacuating several ounces of degenerated tissue. No bare bone could be detected. The boy gained after the opening was made, but later the drainage became unsatisfactory and under ether I made a very free incision five inches long through the entire gluteal region down to the great trochanter; the original opening high up had not drained well and the discharge had produced an abscess cavity of some size lower down. The curettings and walls of cavity were most carefully examined by Dr. Buxton and not the slightest evidence of tuberculous disease could be found, practically verifying the diagnosis of sarcoma. The last operation was done April 10, 1898, and a few days ago (June 1, 1898) the patient's physician wrote me he had gained ten pounds and was feeling very well. The tumor in the iliac fossa has never recurred and the only probable explanation of the trouble in the gluteal region is, I think, that the softened and degenerated sarcomatous tissue worked backward along the line of least resistance and finally became infected. The primary tumor undoubtedly started in the ilium. This case has not yet been reported.

Case 14.—Recurrent round-celled sarcoma of the lip, treated with the mixed toxins.—A little girl, aged 5 years, daughter of a physician. Family history good. Personal history: First noticed a small spot, resembling a mosquito bite, on the right side of the lower lip, in September, 1896. About four weeks later it was removed by Dr. James R. Yocom of Tacoma, Wash. It was not regarded as malignant at that time, but the specimen was kept in alcohol. In October the growth began to reappear. Examination was then made of the specimen previously removed, and it was found to be round-celled sarcoma. A much more extensive operation was immediately done, the entire thickness of the lip being removed, going widely beyond the scar and tumor. The tumor at that time was about the size of a pea and markedly indurated. A few weeks later it again occurred in the region of the scar. Feeling that further operation would be of little avail, the child was brought to me for treatment with the toxins. The tumor at that time involved the entire scar and extended from the mucous membrane of the lip downward

about one and one-half inches, and was increasing rapidly in size. The mixed toxins were begun Feb. 10, 1897, and injected into the tissues of the lip near the tumor and repeated in doses just sufficient to give her a slight reaction, but only once producing a chill. The filtered toxin was given except in two instances. The tumor tissue very soon lost its vascularity, began to shrink and to lose the glossy tense appearance. After four weeks' treatment, there was apparently very little of the tumor tissue remaining, but with a view of decreasing the chances of relapse, by removing any possible sarcomatous tissue that might be present, I decided to excise the entire scar tissue resulting from the previous operation. This was done by making the usual incision adopted in epithelioma of the lip, cutting about one-fourth inch beyond the scar tissue. The tissue removed was carefully examined microscopically by Dr. B. H. Buxton, assistant pathologist to the New York Cancer Hospital, and no sarcomatous elements could be found in any portion of the tissues removed. The child is still free from recurrence, August 1, 1898. The injections of the filtered toxins into the arm have been used with intervals of rest during the past year.

Case 15.—Spindle-celled sarcoma of the abdominal wall. Entire disappearance following thirty injections of the toxins. Patient well at present, one and one-half years afterward. M. S., female, aged 18 years, was admitted to the New York Cancer Hospital Dec. 29, 1896, with a tumor in the lower portion of the abdomen of several months' duration. Exploratory laparotomy was performed by Dr. Joseph Brettauer, assisted by Dr. George W. Jarmon, the attending gynecologist. A large mass was found in the abdominal wall, both intra- and extra-peritoneal, but it had no connection with any of the abdominal organs. It was regarded as inoperable and a portion was removed for examination and pronounced by the hospital pathologists, Drs. E. K. Dunham and B. H. Buxton, as a spindle celled sarcoma. The case was transferred to my service in order to have the toxin treatment tried. The first injection was made Jan. 19, 1897. The toxins used were prepared by Dr. Buxton from cultures of streptococcus that had been passed through fifty-five rabbits, thus attaining a very high degree of virulence. After thirty injections, the largest dose being six minims of the filtered toxins, the tumor had entirely disappeared. Very little pain and discomfort resulted from the treatment, and but four chills occurred the entire time. This case was shown in April, 1897, before the New York Surgical Society. The patient was reported perfectly well May 10, 1898.

Case 16.—Spindle-celled sarcoma of the parotid, twice recurrent, inoperable, successfully treated with the toxins.—W. L., aged 40 years, male, carpenter by occupation. Maternal aunt died of malignant tumor of the breast, which had developed as a result of an injury. In September, 1896, the patient received a slight injury to the left parotid region; the swelling was first noticed early in 1897. It continued to increase in size and in March, 1897, was removed by Dr. J. W. Wright of Bridgeport, Conn. A second and a third operation were performed in April, but the growth was found too extensive to admit of removal. Before the first operation the sub-maxillary glands on the same side had become involved. In July, 1897, the patient was treated for three weeks at the Bridgeport Hospital with the mixed toxins of erysipelas and bacillus prodigiosus, with but little improvement. Physical examination showed the tumor to be four inches in diameter, occupying the entire left parotid region, extending from the angle of the jaw to the orbit, from the external auditory meatus nearly to the angle of the mouth. The tumor was hard, firmly fixed to the deeper structures, with an ulcerated area at the center two inches in diameter; there was a second tumor the size of an English walnut in the sub-maxillary region. August 10, the patient was sent to me by Dr. Wright for further advice. Previous microscopic examination had proved the growth to be spindle-celled sarcoma, and this fact led me to advise further treatment. The patient was treated from August 10 to October 15, at the Post-Graduate Hospital, and being in very good physical condition, much larger doses than usual were administered and the injections were made daily most of the time. Although a chill generally followed the injections the patient was up and about the ward the entire time and lost no weight. A marked improvement was noted at the end of two weeks' treatment. This improvement continued constantly until the middle of October, when there was no evidence of the disease remaining either in the face or neck. The patient was shown before the New York Surgical Society March 22, 1898, in perfect health, with no trace of the tumor remaining. He is still well, July 1, 1898. Two other successful cases (Dr. Johnson's and Dr. Storr's) of inoperable spindle-celled sarcoma, now well, one two and a half and the other four years, treated under my direction, will be found under cases of other surgeons.

Case 17.—Inoperable epithelioma of the chin, lower jaw and floor of mouth. The mixed toxins were used for four months. Entire disappearance. The patient well without recurrence four years afterward. This case has already been fully reported in a former paper. The patient was referred to me by Dr. Geo. R. Fowler of Brooklyn, who regarded it as entirely inoperable. Microscopic examination was made by Dr. William Belcher, pathologist of the Seney Hospital of Brooklyn. It is but fair to say that the microscopic examination was made from frozen sections and I wish to give due weight to whatever doubt there may be attached to the diagnosis. The fact remains that the operation proposed for the condition, by an eminent surgeon, was entire removal of the lower jaw, floor of mouth and portion of the tongue. In view of the dangers attached to this operation and the chances of a speedy recurrence, the surgeon advised against it. The tumor entirely disappeared under four months' treatment with the toxins and the patient continues well four years afterward.

Case 18.—Inoperable carcinoma of the breast. Three times recurrent. Constant treatment with the mixed toxins for two and one-fourth years. Disappearance of the tumor. Patient in good health until the end of this period when a local and general recurrence ensued. This case, although referred to in an earlier paper, has not yet been fully reported. The following is a brief history of it: Mrs. B., aged 40 years, first noticed a tumor in the right breast four years ago, developing shortly after an injury caused by a fall. First operation performed by Dr. Grupee of New York, in January, 1894. It consisted in a partial excision of the breast, the axilla not being opened. In the latter part of 1894 there was a well-marked recurrence, both in the breast and axilla. I operated upon the patient the second time at the New York Cancer Hospital in June, 1895. The conditions found being worse than I had expected, it was impossible to make a thorough removal of the diseased tissue. The glands were distinctly carcinomatous as far as the clavicle; the largest, the size of a large hickory nut, located high up in the axilla, completely surrounded the axillary vein and was so firmly adherent that it could not be removed without resecting the vein, which was not thought advisable. Hence only a palliative operation, consisting of the removal of the free glands and the remainder of the breast, was performed. Local recurrence took place in the center of the cicatrix before the wound had entirely healed and the disease progressed rapidly. The arm soon became swollen and the pectoral muscles showed marked infiltration. I decided to try the effects of the mixed toxins, expecting little more than a temporary retardation. Small doses seemed to have but little effect upon the tumor, but by larger doses the disease was controlled and even showed signs of retrogression; the swelling of the arm likewise improved. A few months later I gave the patient ether and excised the area of local recurrence in the neighborhood of the cicatrix, measuring two by three inches. This was firmly adherent to the periosteum of the ribs so that only a partial removal was possible. The disease quickly reappeared, but by increasing the doses of the toxins and the frequency of the injections, it was soon controlled and cicatrization of the carcinomatous ulcer slowly began to take place, and complete healing had occurred by January, 1896. The tumor in the axilla also decreased so much in size that it could no longer be felt. The infiltrated pectoral muscles became softer and practically normal to the touch. The right arm which, before the injections were begun, measured two inches more than the left, now showed a difference of but one-half inch. The patient had gained ten pounds in weight. The injections were continued in very small doses, one to three minims producing little or no reaction and in no way disturbing the patient in performing her ordinary duties. The patient continued well until the summer, 1897, when there was noticed a slight local recurrence in the pectoral region and shortly afterward an enlargement of the supra-clavicular glands. The toxins were left off for a period of five weeks, during which time the growth was most rapid. A few weeks later enlargement of the liver, jaundice, ascites and all the signs were noted. As early as July, 1897, slight twitchings of the left arm and face were noted; these gradually became more frequent and ended in partial paralysis. All the symptoms increased with great rapidity and the patient died in the early part of December, 1897. Microscopic examination of the tumor showed it to be a typical carcinoma.

The case is of much importance, since it shows that in certain cases at least the toxins do have a marked inhibitory action even upon carcinoma.

Case 19.—Recurrent double carcinoma of breast. This case is one of interest, as it shows that in certain conditions the toxins may be used to advantage in carcinoma, especially in conjunction with partial operation.

Mrs. W., aged 56 years, with decided family history of cancer, first noticed retraction of the left nipple three years ago. One year later she noticed a similar condition of the right breast. The first operation, double amputation of the breast, was performed by Dr. Maurice H. Richardson of Boston on Oct. 8, 1895. Recurrence was first noticed in June, 1896, in the form of small, pea like infiltrations in the skin. These increased in size until they formed a mass, three by four inches in diameter. Dr. Richardson advised against further operation and asked my opinion as to the use of the toxins. I stated that I believed the treatment would prove of only temporary value, and might have no effect. If the carcinomatous area could be removed surgically, I thought the toxins might have some influence in delaying a recurrence, although I did not believe they would prevent it altogether. With a clear understanding of these conditions, Dr. Richardson operated a second time on Nov. 27, 1896, and removed the area mentioned. On January 1, before the wound had entirely healed, new nodules appeared in the outlying skin near the anterior axillary line. The toxins, filtrate, were begun Jan. 10, 1897, and continued in small doses daily for one month. The small recurrence in the skin disappeared. The general condition of the patient, which was had at the beginning, remained about the same, but allowing a short interval of rest, her appetite improved and she felt much better than before the injections were given. The latter were resumed, this time by Dr. Richardson, and given three times a week, the dose being only 10 minims of the filtrate, which produced no chill, but only headache and slight malaise. The treatment has been continued in small doses with frequent intervals of rest up to the present time, June 1, 1898, or one and a half years. There have been four or five small sharply-localized skin infiltrations—the largest less than one-fourth of an inch in diameter. These have been removed under cocaine, and the patient is still well and in better health than at any time during the past year and a half.

(To be continued.)

A SURGICAL TREATMENT FOR HYPERTROPHIED PROSTATE AND HERNIA IN OLD MEN, WITH A REPORT OF TWENTY-EIGHT CASES.

Presented before the Section of Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association held at Denver, Colo., June 7-10, 1898.

BY GEORGE W. JOHNSON, B.Sc., M.D.,
CHICAGO.

No class of patients is more worthy of the sympathy and careful attention of the physician than the unhappy victims of prostatic hypertrophy. To this malady is often added hernia, enterocoele, with adhesions of the intestines, hernial sac and tunicae, and not infrequently there is chronic hydrocele of the cord and multilocular cystic degeneration of the testicle. Already declining from the general organic dissolution of senility, these complications make them a class of patients difficult and unsatisfactory to treat. The constant appeals from this class of sufferers for relief from vesical pain and burning, rectal and vesical tenesmus, frequent and painful urination, retention of urine and its concomitant misery, has demanded of me more than passing notice.

The diseases of the prostate and bladder and their adnexa have been studied by many scientific men, and their researches have done much to mitigate the suffering of this class of patients. That there are still conditions which find no relief from palliative means of treatment, there is no doubt. The failure on the part of medicine in this direction has of late attracted the attention of the surgeon, and his efforts have not been without success.

It is the purpose of this paper to report some experimental work in the surgical treatment of enlarged prostate, as well as the radical cure for hernia in old

men. I wish to impress upon your minds the fact that this radical means of treatment for these conditions was resorted to only after years of suffering and pauperism, and when all other sources of relief had repeatedly failed. I do not propose to discuss diseases of the prostate and bladder in general, and much of the clinical detail leading to a diagnosis calling for surgical treatment, is purposely omitted. The minutæ of examination and the detail technique of operations will be abbreviated as much as possible. An unusually large number of this class of patients have come under my observation the last two years, and I have made a careful study of each case, to try to determine the value of radical treatment, and the class of patients requiring it.

Frequency, Common Varieties and Results of Enlarged Prostate.—Sir Henry Thompson has observed that one-third of all men over fifty-five years of age have some enlargement of the prostate gland, and that a large per cent. of this number suffer from urinary disturbance as a consequence; that the onset is between the age of fifty-five and sixty years, and that it rarely comes on before this age, but may appear later. I am of the opinion that the onset, in many instances, is earlier than this, but does not manifest itself clinically until about this period, depending much upon the exciting cause.

The lateral lobes of the prostate may be greatly enlarged without evil consequences, but should they be so enlarged as to produce mechanical obstruction to the prostatic urethra, or the prostatic urethra itself be enlarged, however small, or as McGill has observed, a band of prostatic tissue be formed about the vesico-urethral portion, difficulty in urinating will result. These conditions, sooner or later, produce distortion of the prostatic urethra, elevation of the vesico-urethral orifice, and obstruction to the return of blood to the bladder. Later on, as a consequence of these changes, there will be dilatation of the bladder, fibroid degeneration of the prostatic sphincter, hypertrophy of the vesical walls, dilatation of the urethra, and renal pelvis, calculus formation and uremia. In some instances there may be prostatic enlargement without evil effects. But a slight pressure upon the prostatic urethra, or a slightly hypertrophied condition of this organ, may produce endless mischief, and yet be entirely overlooked by the physician.

Examination.—A digital examination per rectum should be made in every case where there is suspicion of prostatic disease, and a somewhat thorough knowledge of the diseases of the prostate and bladder is required. Strictures and vesical calculi must be constantly in mind. Palliative treatment should be faithfully tried, for many cases of supposed grave prostatic trouble yield readily to this form of treatment.

Symptoms.—In acute prostatitis there is frequent and painful urination, the pain and sometimes a few drops of blood coming at the close of the act. Distress in the perineum, radiating along the urethra and into the spermatic cords and sometimes down the thighs; rectal and vesical tenesmus and painful defecation. If there is a prostatic abscess forming there will be obstruction to the flow of urine, and, in extreme cases, retention, grave constitutional symptoms and throbbing pain in the perineum and bladder. Cystitis will be present, and on digital examination per rectum, pain and tenderness of the perineum and prostate will be elicited.

Chronic Prostatitis.—The symptoms are practically the same in this condition save in degree. There is usually a history of nocturnal pollutions, impairment of sexual function, pyuria and vague neuralgic pains in the pelvis.

Prostatic Hypertrophy.—In this condition there will be a history of difficulty in emptying the bladder, tardiness in the onset of the flow of urine, and lack of force. A sense of feeling that the bladder has not been emptied after urinating; fullness in the perineum and rectum, especially during and after stool, retention and enuresis, pain and prostration, cystitis and vesical and rectal tenesmus usually make up the clinical history. Stricture and vesical calculi call for a special examination. These symptoms are taken from the clinical history of the cases I shall report, and were commonly met with before a positive diagnosis was made. The patients making up the report have been inmates of the Cook County Infirmary for years, by reason of these infirmities, and represent but a fractional part of those still untreated among the fifteen hundred patients under my charge. I simply selected those suffering most, making a careful examination clinically, physically, and of the urine. They were then confined to bed, and a thorough line of palliative treatment, suitable to each, carried on for from two to three weeks, and sometimes much longer. I shall report them in classified groups, giving a detailed description of the first case of each group. This case will be illustrative of the group. The others are here reported but not read. The groups will be arranged according to the kind of hernia and the operations done. The treatment for all forms of enlarged prostate is the same, consisting of either gonangiectomy or orchidectomy.

GROUP I.

Group I represents cases in which there was bilateral hernia with orchiocele on one side, in which orchidectomy was done upon that side and herniotomy and gonangiectomy upon the other side. Two cases.

Case 1.—Aged 65, bed-ridden, emaciated, gastritis, constipation. Large direct inguinal hernia on right side, with an enormous orchiocele of thirty-six years' duration. On left side was also a hernia, which occupied the scrotum, but was not so large or of so long duration as the one on the right side. Prostate gland was greatly enlarged; had had trouble in urinating for fifteen years; was confined to bed on account of retention of urine; suffered from pain in bladder and rectum; had cystitis and a large amount of residual urine; catheter required and passed with difficulty; was filthy from enuresis; peevish and irritable.

Treatment.—Medicinal treatment consisted of hot vesical douches twice daily of boric acid, nitrate of silver, 1-3000, or bichlorid of mercury 1-10,000. Laxatives, medicated suppositories for pain in rectum. Hot sitz baths, hot fomentations to the perineum and bladder, counter-irritation to the perineum, diluents for the urine, and "milking" of the prostate. This treatment was continued for three weeks, with negative results.

Surgical.—Chloroform anesthesia; incision on right side after Bassini's method; cord, testicle and hernial sac removed from scrotum in mass; cord separated and ligated high up; testicle removed; sac dissected out high up and ligated and stump dropped back into peritoneal cavity. The upper and inner portion of Poupart's ligament and the under and outer surfaces of the conjoined tendon and margin of the internal oblique were freshened with a sharp curette and formalin catgut sutures, No. 3, introduced so as to draw the conjoined tendon and internal oblique above the conjoined tendon over Poupart's ligament, entirely closing the external ring and obliterating the canal. The external wound was closed with silkworm gut sutures and a wet bichlorid of mercury dressing of 1-2000 applied. Herniotomy, after Bassini, with resection of the vas deferens was done on the left side.

Subsequent history.—Recovery from operation uneventful.

Wounds dressed and superficial sutures removed on the sixth day. Union by primary intention. No relief from prostatic trouble for three weeks, when gradual improvement began and continued until complete recovery six months after operation, patient having perfect control of urine, with a gain of fifty pounds in weight.

Case 2.—Aged 72 years. Had been an invalid in Cook County Infirmary for years, with bilateral hernia and prostatic enlargement. On right side was a very large hernia, occupying the scrotum. Same condition on left side, except in degree. Prostate greatly enlarged, with a long history of urinary disturbance, and catheter life. Prolonged treatment gave negative result.

Chloroform anesthesia.—Orchidectomy on right side and herniotomy and gonangiectomy on left side. Recovery uneventful. Sutures removed on fifth day. Primary intention and relief from former distress in bladder after four weeks.

GROUP II.

Cases with bilateral hernia, with either bilateral chronic hydrocele of the cord, or bilateral cystic degeneration of the testicle, with bilateral orchidectomy. Three cases.

Case 1.—Aged 62. On right side was a hernia of fifty-nine years' duration, which was both congenital and acquired. On left side was a large scrotal hernia, of ten years' duration. Prostatic urethra was plainly palpable and hard. Had enuresis and inability to empty bladder, excepting with catheter, for years. Had violent cystitis. Medical treatment negative.

Chloroform anesthesia.—Hernia on right side was found to be both congenital and acquired. The congenital sac—forming the tunica vaginalis was firmly adhered to the scrotum. There was hydrocele of the cord, and cystic degeneration of the testicle. Testicle was removed, true sac dissected out, and made into a tampon. Deep and superficial sutures, as usual. There being also chronic hydrocele of the cord and cystic degeneration of the testicle on left side, this testicle was also removed and the ordinary sutures and dressing applied. Wounds dressed and superficial sutures removed on the sixth day. Recovery entirely uneventful save for a slight attack of melancholia of one week's duration. No urinary symptoms after the fourteenth day. Has taken on flesh rapidly since operation, and is in good general health.

Case 2.—Aged 75. Had been an invalid in Cook County Infirmary since 1892. Had bilateral inguinal hernia with a very large orchiocele on right side. Had suffered for years from prostatic trouble. Had residual urine, and had to use catheter frequently. Medicinal treatment absolutely negative.

Chloroform anesthesia.—Owing to the thin abdominal wall on right side, and the very large opening, orchidectomy was done on this side. Left testicle was found to be cystic and was also removed. Sutures removed on the fourth day, and the patient began to get vesical relief in two weeks. Catheter was not passed after operation. Has had no mental symptoms. Is now entirely free from former prostatic trouble, and is a comfortable old man.

Case 3.—Aged 71. Right oblique inguinal hernia, and chronic bilateral hydrocele of the cord of twenty years' duration. There was bilateral cystic degeneration of the testicles. On right side covering of cord and hernial sac were firmly adherent. Prostate was very much enlarged, and the patient had suffered for years from urinary trouble. Had been an inmate of the Cook County Infirmary at various times for years, and required frequent use of catheter. No relief could be had from medicinal treatment. The hydrocele had been tapped a great many times. Palliative treatment negative.

Chloroform anesthesia.—Both testicles removed. Union by primary intention. Convalescence entirely uneventful. No mental disturbance. After one month is free from former prostatic trouble, and in splendid general health.

GROUP III.

Cases with hernia and large enterocele and cystic testicle on one side, with castration on that side and gonangiectomy on the other. Twelve cases.

Case 1.—Aged 82. Right inguinal hernia of fifteen years' duration. Hernia has been strangulated three times. Was filthy from enuresis. Prostate enormously enlarged and hard to the touch. Has had retention, at times requiring catheter. Chronic cystitis. Medical treatment negative.

Chloroform anesthesia.—Right testicle removed, and left was resected. Became confused mentally a few days after the operation, with delusion of wealth and power. Was exalted, sang and exhorted at night. Urinalysis showed albumin, for

which he was vigorously treated, resulting in almost instant relief from mental trouble. He began to improve at once, and made a splendid recovery. Three weeks after the operation he was taken by his daughter, at which time he was almost entirely free from his prostatic trouble.

Case 2.—Aged 64. Right complete inguinal hernia of thirty-nine years' duration. Right testicle was cystic. Hernial sac was divided into three pockets leading from a diverticulum. Sac was greatly adherent to tunica and scrotum. Prostate was enlarged and had trouble from his urine, from which he could get no relief. Catheter required to remove residual urine.

Chloroform anesthesia.—Right testicle was removed and gonangiectomy done of left side. Primary union. Sutures removed on fifth day. Nine weeks after operation has no urinary trouble whatever. Is entirely well.

Case 3.—Aged 68. Strangulated left inguinal hernia. Was a suffer from prostatic hypertrophy, and during the operation for strangulated hernia, bilateral gonangiectomy was done. Fifteen days after operation patient was up, and since then has been very well, and working hard for a farmer near the Institution. He thinks his bladder trouble was due to the "rupture."

Case 4.—Aged 75. Right oblique inguinal hernia of but one and one-half years' duration. Right testicle very much enlarged and cystic. Gives a history of urinary disturbance for years. Enlarged prostate. Has to use catheter at times. Medicinal treatment negative.

Chloroform anesthesia.—Right testicle removed, and left was resected. Made an uneventful recovery, and is entirely free from prostatic trouble, three months after operation.

Case 5.—Aged 61. Enormous right side inguinal hernia occupying the scrotum, and of thirty-five years' duration. Prostate enlarged, with urinary disturbance of a number of years. Residual urine drawn by catheter. Medical treatment gave negative result.

Chloroform anesthesia.—On incision the hernia was found to be both congenital and acquired. The true hernial sac was dissected away from that which enclosed the testicle and cord. An incision was made into the congenital sac and the cord was ligated and cut off. The upper portion of this sac was ligated and dropped back into the peritoneal cavity, while the lower portion and testicle were removed. The true hernial sac was returned above the ring as a tampon. The left vas was resected and in this case braided silk was used for the deep sutures. The external wounds healed by primary intention, but after two weeks a fistulous opening formed and the silk sutures had to be removed. This delayed convalescence. Six months after the operation there is no recurrence and patient is entirely well and free from prostatic trouble.

Case 6.—Aged 75. Had a large inguinal hernia on right side which extended into the scrotum. Was of a great many years' duration. Could not remember how long. Was suffering from retention and enuresis. Required frequent use of catheter to draw off residual urine. Medical treatment negative.

Chloroform anesthesia. On incision the hernia was found to be congenital. An incision was made into the congenital sac and cord ligated and cut away. Testicle removed. Acquired sac returned as tampon. Left vas resected. Recovery uneventful. Prostatic disturbance gradually disappeared, and is now in splendid general health five months after operation.

Case 7.—Aged 76. Right inguinal hernia of twenty-six years' duration. Prostatic urethra plainly palpable and very hard. Was suffering great agony from retention. Had had enuresis and general urinary wretchedness for years. Cystitis; catheter required. Medical treatment absolutely negative.

Chloroform anesthesia. Right testicle being cystic was removed. Left vas was resected. Recovery entirely uneventful and complete in one month.

Case 8.—Aged 61. Very large scrotal hernia of fourteen years' duration. Could not be reduced, owing to adhesion to scrotum, and of the intestines to the hernial sac. Was a good tailor, but was unable to work on account of pain from hernia and bladder trouble. Faithful palliative treatment negative.

Chloroform anesthesia. Incision down upon the sac. Adhesion between sac and scrotum broken up. Incision into the sac, and the intestines carefully separated, though leaving many raw surfaces. Intestines returned to peritoneal cavity and sac tied off. Cord ligated and testicle removed. The opening through the abdominal wall being so large three rows of sutures were put in, beginning with peritoneum, Poupart's ligament, internal oblique and conjoined tendon. Fascia of external oblique to margin of Poupart's ligament. Left vas was resected. The bowels were kept active with salines and the patient made a beautiful and uneventful recovery. Three weeks after operation was perfectly free from any of his former trouble and has resumed his work.

Case 9.—Aged 55. Incomplete right inguinal hernia, seven years' duration. Has had urinary disturbance for ten years. Large amount of residual urine, requiring use of catheter.

Chloroform anesthesia. Orchidectomy on right and gonangiectomy on left side. Temperature normal after sixth day. Sutures removed on fifth day. Did not require catheter after operation and in two weeks began to get relief from urinary trouble. Recovery complete.

Case 10. Aged 68 years. Right complete inguinal hernia and large enterocele, of forty years' duration. Has had urinary disturbance for almost forty years. Had attacks of retention. Is constantly affected with enuresis, pain in bladder and rectum. Had cystitis. Had been under medical treatment at times, for a year, and under special palliative treatment for three weeks, with negative result.

Chloroform anesthesia. Incision as after Bassini's method. An enormous sac was found to occupy the scrotum. There was also varicocele. Testicle removed. Sac dissected out high up and tied off. External inguinal opening completely closed with formalin catgut sutures. Gonangiectomy was done on left side. Union by primary intention. Sutures removed on fifth day. Six days after operation improvement in urinary trouble began, but even after this, there were times when patient was filthy. Temperature normal after fifth day, and six weeks after operation is entirely free from former trouble. Prostate atrophied and feels soft to touch. Left testicle also seems smaller.

Case 11.—Aged 72. Bilateral inguinal hernia, but much larger on the left side. Prostate enlarged. Urinary disturbance.

Chloroform anesthesia. Bassini's method was done on right side with gonangiectomy. On left side there was found to be a large enterocele with intestines matted together and firmly adherent to sac and tunica. Testicle was cystic. Adhesions were broken up and intestines reduced. Orchidectomy was done. Recovery uneventful and seven weeks after operation is entirely well. Prostate is smaller and testicle on right side is also diminishing in size.

Case 12.—Aged 75. Left complete inguinal hernia of thirty years' duration. Enterocele, cystic testicle and chronic hydrocele. Enuresis. Prostate enlarged, residual urine and catheter.

Chloroform anesthesia. Orchidectomy on left side and gonangiectomy on right. Convalescence entirely uneventful and one month after operation appears perfectly well. Taken from institution by his son five weeks after operation.

GROUP IV.

Cases in which herniotomy was done on one side, with bilateral gonangiectomy, Fowler's method for hernia being used. Five cases.

Case 1. Aged 60. Left inguinal hernia. Prostate greatly enlarged. Enuresis. Inability to control urine. Residual urine, requiring catheter. Burning pain in penis and bladder. Rectal tenesmus. Medicinal treatment negative.

Chloroform anesthesia.—Incision down upon the sac. Hernia found to be congenital. A circular incision was made around the sac and an incision laterally on upper portion of sac to internal ring. Cord drawn out of the sac through lateral incision and the sac ligated. Lower portion of sac left to form tunica for testicle. Then, after Fowler's method, an incision was made through the transversalis fascia up to the deep epigastric vein and artery. These were ligated and cut through. The cord with the vas was resected and cut ends touched with 95 per cent. carbolic acid; was dropped below the transversalis fascia and this fascia sutured over it. The remainder of the operation was done after the usual method. The right vas was resected. The time consumed in this operation was more than I generally take, owing to the herniotomy being done after Fowler's method, which is equivalent to doing a laparotomy. The patient made a good recovery, and was entirely relieved from his distressing urinary symptoms after three weeks.

Case 2.—Aged 66. Right inguinal, scrotal hernia of seventeen years' duration. Vesical and rectal distress from obstruction to prostatic urethra. Residual urine, requiring catheter. Medicinal treatment negative.

Chloroform anesthesia. Fowler's operation and gonangiectomy on right side, with gonangiectomy on left side. Operation and subsequent condition a success. No urinary disturbance after six weeks.

Case 3.—Aged 65. Left inguinal hernia with a tendency to become strangulated. Was of three years' duration. Prostate greatly enlarged and nodular to touch. Was filthy and offensive from enuresis. Was a great sufferer from retention and residual urine, and cystitis. Had to be catheterized, which was difficult. Medical treatment was persisted in, but brought no relief.

Chloroform and ether anesthesia.—Herniotomy after Fowler's method was done, with bilateral gonangiectomy. Patient became confused mentally after operation, and was very filthy and hard to manage. But after three weeks his mind cleared up somewhat and he was allowed to get up, after which he improved and, though suffering from senile dementia, is greatly improved as to urinary disturbance.

Case 4.—Aged 62. Right complete inguinal hernia of three years' duration. Suffered a great deal from prostatic trouble. Had cystitis and enuresis and at times retention. Catheter had to be used. Herniotomy after Fowler was done, with bilateral gonangiectomy. Was up three weeks after operation, and is now entirely free from any of his former prostatic trouble.

Case 5.—Left direct inguinal hernia, of three years' duration. Prostatic hypertrophy with clinical history of two years' trouble, more aggravated at times. After failure from palliative treatment, Fowler's operation for hernia with bilateral gonangiectomy was done. Result entirely satisfactory as to operation, and relief from vesical distress complete in nine weeks.

GROUP V.

Cases in which there was ventral and femoral hernia, with bilateral gonangiectomy. Two cases.

Case 1.—Aged 63. Had a large ventral hernia in median line, about midway between umbilicus and symphysis pubis, of three years' duration. The tumor was pedunculated and could not be reduced. It made pressure upon the bladder, and was a constant source of irritation. The patient has been a long sufferer from prostatic hypertrophy, and was a constant sufferer from retention and use of catheter. An endless amount of treatment brought no relief.

Chloroform anesthesia.—An incision through the integument over the right lateral portion of the tumor revealed that the tumor was made up of omentum. The omentum was ligated off in sections and removed. The wound was closed by suturing separately the layers of the structures of the abdominal walls. Bilateral gonangiectomy was done. The patient, being a syphilitic, made a tedious recovery. The wound suppurated, and patient was removed from surgical ward four days after operation. Eventually, however, he made a good recovery and became much more comfortable than before the operation. The result was not so satisfactory to me, from a surgical point of view, as the others I have done.

Case 2.—Aged 67. Had a large ventral hernia over site of former appendicitis operation; also a large femoral hernia on same side. He was anemic and despondent through failure to get relief from distressing symptoms of long duration, caused by enlarged prostatic urethra, which had always been diagnosed as a deep-seated stricture.

Chloroform anesthesia.—A long incision was made along outer surface of old cicatrix down to femoral opening. The hernial sac was then dissected out, beginning at the neck of the sac, which was ligated high up as possible and cut away. The falciform, crural and pectineal fasciæ, Poupart's and Gimbernat's ligaments were accurately approximated with No. 3 formalin catgut sutures. The ventral opening was also closed by carefully suturing the respective layers of the fascia and muscles with the same kind of sutures. The cicatrix was cut away, and the external wound closed with interrupted silk-worm gut sutures. The result of this operation was perfect, the patient is greatly improved in every respect, as there was resection of both vas deferens.

GROUP VI.

Cases in which there was either bi- or unilateral hernia, with herniotomy and bilateral gonangiectomy. Three cases.

Case 1.—Aged 66 years. Bilateral hernia of twenty years' duration. Left hernia appeared first; had been strangulated; has had enuresia and vesical distress for three years.

Chloroform anesthesia.—Bassini's operation and gonangiectomy on right side. On left side was an enormous enterocele with intestines firmly knotted together and to the hernial sac. The adhesions were separated and intestines reduced. Sac tied off high up and cut away. Gonangiectomy was done on this side also. Patient took the anesthetic badly, requiring rapid operation. Sutures removed on fifth day after operating and temperature was normal at this time. Was up in three weeks, and five weeks after operation seems entirely well. Prostate diminished in size and testicle smaller.

Case 2.—Aged 64 years. Incomplete right inguinal hernia of eight years' duration. Has had urinary disturbance for

seven years; enuresia, vesical pain and burning. Never had to use catheter.

Chloroform anesthesia.—Bassini's operation on right side with resection of two inches of vas. Gonangiectomy on left side also. Recovery uneventful. Remained in bed four weeks, as his abdomen was pendulous and recurrence more liable. Five weeks after operation is entirely well. In this case, where the vas deferens was resected on left side, there has appeared a hard mass at each cut end of the vas the size of an acorn; is not painful and is easily movable.

Case 3.—Aged 73 years. Left side inguinal hernia of four months' duration. Has had enuresia and vesical distress for three years, also pain in the back, rectum and perineum. Residual urine, requiring use of catheter at times.

Chloroform anesthesia.—Bassini's operation on left side with bilateral gonangiectomy. Six weeks after operation still complains of pain in the back, but is entirely free from urinary disturbance, except for slight burning after urination. Testicle somewhat smaller than at time of operation.

GROUP VII.

Case in which there was simple bilateral gonangiectomy. One case.

Case 1.—History of difficult urination for three years, with enuresia, retention, frequent and painful urination, rectal and vesical tenesmus, residual urine and enlarged prostate. Catheter passed with the greatest difficulty and then with only the smallest size, the obstruction being in the prostatic urethra. Medical treatment negative.

Chloroform anesthesia.—Bilateral gonangiectomy of one and one-half inches of the vas deferens and patient walked from the operating room. There was no rise of temperature. Catheter was not required after operation, and in ten days patient began to get relief from former urinary disturbances.

1. All these cases were confined to bed, and a thorough line of palliative treatment carried on for from three to four weeks. If no benefit resulted from the palliative treatment, the patient was transferred to the surgical ward, when for two weeks before operation a stimulating diet with plenty of whisky and large doses of strychnia were administered. During this time the field of operation was carefully prepared with green soap, alcohol and bichlorid of mercury compress. The most rigid asepsis was followed through the preparation of the patient and the operation, with magnificent results in every case but one. The superficial sutures were always removed on from the fourth to the sixth day after the operation, and two dressings were all that were required.

2. Bassini's method for hernia was used in all but five cases. These were done after Fowler's method, which seems very surgical to me.

3. In cases where a large mass of the intestines occupied the scrotum, I returned them to the abdominal cavity three or four days prior to the operation. In some cases there were adhesions preventing the reduction.

4. No incisions were made into the scrotum in any case except into a small portion of the upper third, and even in cases of orchidectomy no drainage whatever was used. Hot sterilized salt solution of one dram of salt to a pint of water was used to control all oozings.

5. Chloroform anesthesia was used in all but one of these cases, and in this ether was substituted. Though old men with sclerotic arteries, and in many instances very feeble, no evil consequences resulted from operation.

6. Mental symptoms appeared in only three cases, and in these instances I believe they were due to the presence of albumin in the urine, as albumin was found which was not present before the operation, and when treated gave immediate relief to mental symptoms. I would caution all operators to look well to this suggestion, as in some reported cases acute

mania developed after bilateral gonangiectomy. In a case related to me the mental trouble disappeared as soon as the albuminuria was treated.

7. No recurrence has taken place in any case of this series, and they have been followed up to this time.

8. In every one of these cases there has been complete relief from all former urinary disturbances, and the herniotomy has rendered the patient very much less helpless. Most of the operated cases were kept in bed for from a month to six weeks, with the hope that better organic union would result, and thereby lessen the liability to a recurrence.

9. From my experience I have no hesitancy in giving out the opinion that with proper study of the case for diagnosis, good preparation and rapid operating, this class of patients can be successfully treated for these grave maladies, with but little risk to life. And although it is a heroic treatment, it must be admitted by all who have had any experience with the treatment of this class of patients, it is warranted, in that it renders old men comfortable and less helpless than any other method of treatment. All of this series were grave cases of long duration, and although the best of preparation was made, the extreme age and feeble condition of many made it seem almost impossible for them to survive the operation. Yet not a single accident has occurred; and the results have been more than could be hoped for. The relief from distressing urinary disturbance has not been as immediate in any of these cases as in some reported; but no case has failed to be benefited, and in the most obstinate cases relief began to appear not later than the third week after operation. In cases where bilateral orchidectomy was done, the patient became almost obese and greatly improved in general health. In every case there was a diminution in the size of the prostate, and in the cases where gonangiectomy was done, the testicle also became much diminished in size.

10. *Urinalysis.* In all the cases here reported pus was present in considerable quantity, and the reaction was alkaline, the reaction being taken as soon as the urine was voided. On standing, the pus settled in a sticky, viscid mass, which showed the cystitis to be of a chronic character. Blood and albumin were usually present in small quantities. The staphylococcus pyogenes aureus, albus and citreus, and the streptococcus pyogenes, as well as the bacillus coli communis were usually present. Vesical epithelium was also always found. The appearance of the urine was turbid and the odor ammoniacal, the sediment sticking to the graduate on standing. Previous to my service these patients had been in the habit of catheterizing themselves, and I have no doubt that this made their cases very much more aggravated.

11. In no case was the *libido sexualis* retained that I am aware of.

12. All cases should be given a thorough line of palliative treatment with confinement to bed. In this series, of those so treated, one in four required no surgical treatment.

RÉSUMÉ OF THE LITERATURE OF CASES OF ORCHIDECTOMY OR GONANGIECTOMY IN CASES OF HYPERTROPHY OF THE PROSTATE.

Ramm,¹ of Christiania, Norway, was the first (?) to

¹ There is now no doubt that Dr. Francis L. Hayers was the first operator to do orchidectomy or gonangiectomy for hypertrophied conditions of the prostate.

perform the operation of castration for the relief of hypertrophy of the prostate. He did the operation in April, 1893, and reported two cases.

Case 1.—Aged 73. Dysuria for fifteen years. Prostate was the size of an apple. The patient was catheterized for two years; urinated every hour, did not empty the bladder, and prostate was only over-ridden by catheter when two fingers were introduced into the rectum. The patient had advanced chronic cystitis. The urine was foul and contained blood. Three days after the operation the size of the prostate was diminished very materially, and at the end of some months the patient passed water twice at night, and three or four times during the day.

Case 2.—Aged 67. Sixteen years previously the patient was treated for retention of urine. Ten years later a suprapubic puncture was made for the relief of the retention. Before the operation the patient's bladder was distended nearly to the umbilicus, and catheter was passed with much difficulty. The night after operation he passed eighty c.c. of urine in a jet. Prostate diminished rapidly in size. Ten days after the patient passed water seventeen times in twenty-four hours, while two months after the operation he was compelled to urinate about five times a day, and once at night. The prostate felt soft.

Dr. Ramm summarizes his views as follows:

1. After castration of adults the prostate shrinks.
2. Hypertrophic prostate shrinks after castration, beginning a few days after operation.
3. Shrinkage of volume of the prostate can be used after double castration as a means of removing the mechanical obstacle to urination. (*Centralblatt für Chirurgie*, Vol. 21, pp. 387-388.)

Haynes was the first in America to perform castration for the relief of hypertrophied prostate.

Case 1.—Double castration in a case of prostatic hypertrophy where the symptoms lasted for two years. Eighty-four days after operation "the patient was actually cured."

Case 2.—Complicated by acute cystitis and morphin habit. Catheter inserted every two hours. Double castration. After operation cystitis disappeared and patient passed urine spontaneously. Use of catheter every five hours. Morphin habit also cured.

Case 3.—Patient operated on fourteen days prior to the time the case was reported. Catheterization was almost impossible owing to the abnormal development of the prostate. Result not stated. (*New York Med. Journ.*, 1895, Vol. 61, p. 584.)

M. Rochet remarks that castration for hypertrophy of the prostate may be considered as a barbarous method, and that deferent resection, simple or double, is far from having established proofs. (*Lyons Médical*, Janvier 2, 1898.)

Sir Henry Thompson says that one man of every three over 55 years of age, examined after death, showed some enlargement of the prostate; one out of every seven had some degree of obstruction present; while one in fifteen had sufficient enlargement to demand some form of treatment. In this country, according to the last census, there are more than three million men over 54 years, and of those, according to Thompson's estimate, about two hundred thousand are sufferers from hypertrophy of this gland. The classification of the remainder White arranges as follows:

1. The condition of the prostate as to size and density.
2. The amount of pain.
3. The amount and character of residual urine.
4. The frequency of catheterism and its ease or difficulty.

As secondary conditions, he notes: 1, the age; 2, the sexual power; 3, the conditions of the kidneys; 4, the general condition.

White divides the 200,000 cases into groups.

Group A, patients with moderate enlargement; little or no pain; clear residual urine to the extent of

three or four ounces, and who never use catheter. If patient is not old, he retains sexual power; sound kidney; castration should not be considered.

Group B includes patients with large prostate the size of a lemon, with eight or ten ounces of residual urine, and with difficulty in the introduction of catheter. Then the choice lies between vasectomy, castration and prostatectomy.

Group C includes patients with prostate from the size of an orange to that of a base-ball. Cystitis is marked and the catheter introduced with difficulty. In these cases castration is preferred; also vasectomy may be first tried.

Group D, desperate cases, those in which the prostate is enormous, the cystitis excessive, the bladder dilated and atonied; retention; catheterization difficult, and occasionally impossible. Such patients are generally of advanced age and suffer from toxemia—a combination of uremia and sapremia.

Castration under these circumstances offers far more hope of benefit and less risk than any other operative procedure. In this class of cases the mortality is high.

As to the prospects of cure after operation, White says that in every thirteen cases of recovery, we should count upon eleven being complete cures. He states that clinical experience justifies the assertion that in a large proportion of cases (thus far in approximately 87.2 per cent.) rapid atrophy of the prostatic enlargement follows the operation; and that disappearance or lessening in degree of long standing cystitis (52 per cent.), more or less return of vesical contractility (66 per cent.), amelioration of the most troublesome symptoms (83 per cent.), and a return to local conditions not very far removed from normal (46.4 per cent.) may be expected in a considerable number of cases.

The mortality in castration is 18 per cent.; in vasectomy, 12 per cent. But it must be remembered that the patients in Class D, or worse, patients actually dying from uremia or sepsis, have been subjected to these operations. It is important to note that even in the desperate cases which make up the series of deaths, 75 per cent. showed improvement of symptoms or of shrinkage of the prostate before death (*University Medical Magazine*, 1897, Vol. ix, p. 469).

(To be continued.)

SOME RECENT OBSERVATIONS UPON ACUTE INFLAMMATION OF THE PROSTATE GLAND.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY LISTON HOMER MONTGOMERY, M.D.

CHICAGO, ILL.

I selected my topic, even at the risk of promulgating but few new ideas and as well, no doubt, of going over much ground that you are already familiar with.

Anatomy of the gland.—In brief, the prostate gland in structure as well as in function is rather a muscle than a gland, composed chiefly of unstripped muscular fibers, and has an inner or circular layer which is continuous in front with those surrounding the membranous urethra and behind with the muscular coat of the bladder. The outer layer beneath the fibrous capsule forms a sheath for the gland, while beneath them the glandular structure is imbedded, or, accord-

ing to Park, the prostate, its utricle; the dilated extremities of the vasa deferentia (called ampulla), and the seminal vesicles are, like the uterus and tubes of the female, enclosed in a thin fibrous sheath, which he has called the broad ligament of the male. The gland is divided into two lateral lobes by a deep sulcus or notch posteriorly and by a furrow at the upper and lower surfaces, while the so-called middle or third lobe, is the portion situated between the two lateral lobes at the under side and the weight of posterior part of the gland, adjacent to and beneath the neck of the bladder. The prostate in normal health is one-half ounce in weight and is about the size of an ordinary horse chestnut.

Varieties of inflammation.—There are two varieties of acute prostatitis—the follicular and the parenchymatous, either of which may be partial or complete as well as acute or chronic. Discussion of the latter grade of this disorder, however, does not come within the purview of this paper.

The follicular forms when resulting in abscess are rarely large, and almost invariably discharge themselves into the urethra, while the acute parenchymatous variety is more serious, because the entire substance of the gland is inflamed (as in a sort of cellulitis) and great disorganization may occur, involving the entire glandular and connective structures of this complex organ.

Etiology.—Acute prostatitis, whether it results in abscess of the gland or not, as is well known, may be due to trauma, or it may occur as an abscess—frequently does—elsewhere in the human economy, due to a probable remote predisposing cause, or due to causes wholly idiopathic in character. Among the latter may be enumerated a natural tendency toward a delicate constitution, which, when produced in an idiopathic manner, is not frequently seen.

The causes regarded as traumatic which may induce this disease not only include the incautious introduction of instruments; a contusion to the perineum, vesical and rectal tenesmus, obstinate constipation, formation of scybali and hemorrhoids with their incidental phenomena may also be a direct cause to bring on the disease. Gonorrheal infection, when unchecked and extending to the prostate, is almost invariably regarded as one of the most frequent exciting causes of the disease, as the tissues about the gland are a formidable soil for the growth of pus bacteria and its sequelæ.

The disease has been known as a complication in certain forms of acute febrile disease. It has been reported also as a sequel of smallpox, scarlet fever, typhoid and typhus fever. The various toxemias of infectious fevers produce venous stasis, which endangers the endothelium of the organ, or where there is a transudation in the blood vessels, as osmosis, or an altered condition of the blood which involves a malnutrition with nerve disturbances in the gland, or an altered blood plasma that results in congestion of the gland and prostatic plexus of veins may all be regarded as excitants to induce the disease; particularly is this true in old persons. Although doubtless extremely rare, infection from various forms of rectal disease, due to the proximity or proximity of those parts, may be regarded as a possible exciting cause, notwithstanding the firm capsule of the gland. It would seemingly offer a sufficient obstacle and prevent the entrance of germs through that channel. On the theory of using instruments;

strong injections, horseback riding and, I have excellent reasons for believing that too much bicycle-riding will produce the disease, due to the rider assuming a false position on the saddle, or attributed to some possible faulty construction of the saddle, producing jolting, jarring, over-exertion, etc., resulting in irritation, congestion and disease of these vital structures. Sudden shocks about the perineum, induced in whatever manner, may be an exciting cause of this difficulty. Purulent or putrid cystitis, or pyelonephritis may also induce the follicular variety of the disease, although as has been stated hematogenous prostatitis is comparatively a rare disease. Should it occur, however, it would be expected to be due to a deficiency or reduction of oxyhemoglobin in the red corpuscles throughout the body.

Stricture of the urethra when long neglected may well be regarded as an active factor in exciting this disease, and some authors have said that a contracted meatus and phymosis are causes. If this be true, it is doubtless due on the same theory as stricture, namely, that at times of micturition a free exit of urine is not voided with the facility in which this act should be performed. Syphilis is said to be an exciting cause, and calculi, especially when retained in the bladder in the vicinity of the gland, is another exciting cause to produce inflammation of it.

Taking cold, which first induces congestion and subsequently is followed by inflammation of the gland, is also an exciting cause. Too frequent indulgence in alcoholic beverages and other causes that induce a sexual hyperemia followed by irritation or excitation of the gland, are doubtless true causes of a certain proportion of this distressing and sometimes serious malady. Excessive purgation is mentioned by Bumstead as a cause. Cantharides and other irritant drugs are cited as a cause by Loomis and Thompson. Senility doubtless is a contributory cause in a certain proportion of cases.

Urinary infiltration and frequent retention of the renal secretion, whether it is of an abnormally acid or alkaline reaction, may induce the trouble. On the other hand, the stream of urine is greatly diminished in size, or retention may occur and be due to the inflamed gland, or to an edematous condition of the gland or to infiltration of exudative matter around it (as will be stated later), to the formation of purulent matter within the prostate. Vasomotor disturbances that induce edema and hyperemia may cause inflammation of this gland; cellular exudation or serous exudation, especially in a neurotic subject, may induce either form of the disease in persons whom for want of a better term, I have denominated those who are prone to "idiopathic prostatic neurosis."

And lastly, I may mention that vague cause, "due to reflex disturbances," as a possible or probable one under certain conditions that would be likely to excite inflammatory action of the gland. Hypertrophy, atrophy, tubercle, malignant disease, etc., will not be considered as exciting causes of the disease in the strict sense and literary construction of the title of this paper.

Age.—Recent observation has led me to believe (according to my experience) that it is most frequently met with between the ages of 25 and 40 years, although as per the foregoing remarks, idiopathic or traumatic cases may supervene at any period of time after this limit, the former particularly, when the person afflicted is of a rheumatic or gouty diathesis.

Symptoms.—The symptoms that lead the surgeon to suspect inflammation of the prostate gland are the following: After eliciting a personal history of the case, and if the premonitory symptoms do not subside there is increased pain about the gland. There will be some difficulty in micturition and great pain experienced in bowel movement, often spasmodic in character when the patient tries to void his urine, accompanied by great distress and irritability of the neck of the bladder. Nervous chills followed by fever will give rise to strangury, and symptoms of a septic nature may supervene, in addition to which there will be nausea and restlessness. One of the early symptoms of the process of suppuration is a throbbing sensation accompanied by a dragging down weight and feeling of distention about the rectum, perineum, sacral region and neck of the bladder; this may extend to the lower part of the abdomen and suprapubic region as well as to the distal end of the glans penis and scrotum. There is also loss of appetite, constipation, a furred tongue, emaciation, anxious facies, despondency and dread of an operation.

Diagnosis.—In this it may be difficult to decide whether the disease is circumscribed and wholly of the gland, or whether it be periprostatic in character.

Wyman says that "this affection is one which is entirely overlooked until it manifests itself by a gush of pus from the urethra or rectum, and rarely into the cavity of the perineum." Ziegler says "inflammation of the prostate gland is often associated with inflammation of other parts of the urogenital system, such as gonorrheal urethritis, purulent or putrid cystitis, etc., and that hematogenous prostatitis is rare." A digital examination (*tactus eruditus*) per rectum or manipulation bi-manually, will disclose that the gland is excessively sensitive and much enlarged. The anterior wall of the gland or its corporeal portion projects or is pushed into the bowel. If the feces are inspissated, defecation is most distressing, and so acute is this that the pain radiates along the hypogastric plexus of nerves.

Prognosis is usually favorable, as the disease in the majority of cases will result in recovery, either as a result of resolution or suppurative process with spontaneous discharge into the urethra or rectum, or in a few instances that I have seen, by both of these channels. Occasionally death will ensue through the intervention of sepsis, subsequently, if a morbid condition of the gland remain. Such defect must be ascertained, then, if possible, corrected.

Treatment.—In general the patient should be confined to bed and placed upon a milk diet; early application of leeches to unload the engorged prostatic plexus of veins, and hot fomentations to the perineum followed by free evacuations of the bowels with saline aperients. Copious draughts of demulcent drinks to dilute the urine should be administered. Hot hip baths, twice or thrice daily, should be given, although Wyeth recommends that "ice bags applied to the perineum will be found agreeable and of value," and that "suprapubic aspiration may be demanded in severe cases."

On the other hand, DaCosta says, "adjust hot sand-bags to the perineum and hypogastrum." If the abscess has burst into the urethra and the stream of urine is very small, it may be necessary to introduce by most gentle methods a soft india rubber catheter, well oiled. Do not use metallic catheters if you can avoid doing so, and at as early a period as possible

dispense with all kind of catheterization. A gentle massage process to favor the discharge of pus is indicated in certain cases. If shreds of mucus casts collect, compared to croupous exudation as stated by Van Buren and Keys, and are cast off per urethram, do not mistake these for spermatorrhea.

Enough anodyne and hypnotic remedies should be administered per ore or in suppositories to assuage pain, and if a soft catheter should have to be resorted to and the pain is excruciating, this can be facilitated under local anesthesia, and in a few instances if stricture is present, electrolysis to dilate the urethra may be found necessary.

My plan consists primarily, after ascertaining by examination, if suppuration has occurred, if possible, in washing out the abscess cavity with hydrogen peroxid to favor the exit of discharge. In no instance do I retain a drainage tube *in situ*, as it retards the closure of the fistulous opening. This is followed by a copious enema of as hot water as can be well borne and injected into the rectum. Hot hip baths at a temperature of 105 degrees F. to 110 degrees F. should be given as frequently as seem agreeable to the feelings of the patient. Avoid administering morphin internally if you can. Do not permit the patient to strain at stool nor while he is voiding his urine, as this will surely aggravate the symptoms.

On the theory, as above stated, that toxins are retained in the circulation and within the gland, and the disease, when it continues, acts on the nervous system, intricate microscopic changes having occurred, and with the view of preventing degeneration in the gland substance, I administer freely *tritium repens* or fluid extract of tritipalm as a genito-urinary tonic in combination with infusion of gum arabic or flaxseed. Along with these remedies the mineral waters, particularly Vichy and citrate of potash, go well together. Hydrate of chloral or this salt combined with the alkalines of antikamnia and the bromids are the very best anodyne remedies to control pain and spasms of the neck of the bladder. These pharmacologic or medicinal remedies are the most logical to use in my judgment, while externally, applications of antiphlogistine, inunctions of a 10 or 20 per cent. of iodoform, lanoline preparation, as well as of mercury, are also of much value.

I have also resorted to the internal administration of fluid extract *secale cornuti*, alternated with iodid of potash, with the view to restore contractility of the gland and to favor absorption of the plastic material deposited in it. The application of electricity and of the galvano-faradic current to the prostatic urethra may be tried to obtain similar results.

Secondly and lastly; a cheerful prognosis should be given to the patient, as well as substantial general tonics that are readily assimilated and will be most likely to produce metabolic action, are indicated to bring about complete convalescence.

If time permitted, I would recite the histories of several interesting cases in detail, but I am well aware that the Section know these general ideas find characteristics without my taking further time to do so.

VENTRAL HERNIA AFTER APPENDECTOMY.

Presented to the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY M. M. JOHNSON, M.D.

HARTFORD, CONN.

The immediate consideration in appendectomy is the saving of life and the restoration to health of the individual patient. Many operations with a faulty technique have accomplished this. The remote consideration is the integrity of the abdominal wall. This necessitates a careful consideration of the operative technique and the avoidance of many unnecessary procedures in the after-treatment which interfere with the closing of the wound.

The frequency of ventral hernia after appendectomy is inferred from the fact that fifty cases referable to this cause, were observed at the Hospital for the Ruptured and Crippled, in New York City, in two years. (Coley.) A still greater evidence is the great demand for trusses and supporters of the various kinds by those upon whom the operation has been performed.

Incisions.—There are seven well-recognized incisions: The V-shaped; the L-shaped; the T-shaped; the obtuse angle; the long straight; the short straight; and McBerney's well-known incision, where the different layers are cut at different angles. These may be classified as the *long* and *short* incisions. When considering the relation these incisions bear to ventral hernia, we are confronted with the following facts:

1. Nerve supply, according to Woolsey (*Annals of Surgery*, Jan. 1898, p. 3), who points out the most important element in abdominal surgery as the nerve supply, comprising the six lower dorsal, the ilio-hypogastric and the ilio-inguinal nerves. Their motor portions pass, for the most part, between the internal oblique and the transversalis muscles, which, together with the external oblique, they supply, and then they pierce the sheath of the rectus muscle to furnish its motor nerve supply. "Their division causes paresis and atrophy of the muscles, weakens the abdominal wall and predisposes to hernia." Therefore, the longer the incision the more nerve fibers will be severed, thus increasing the chances of ventral hernia.

2. The making of the incision as much as possible through muscular tissue, according to Woolsey and McBerney, is open to well-founded objections. When the contracting and relaxing function of the muscles is taken into account, it is evident that the cicatricial tissue is constantly subject to a powerful tension, followed by relaxation, which when long continued has a tendency to weaken the cicatrix, and in time it gives way and is a factor in the causation of hernia.

3. The after-treatment should be as free as possible from undue irritation. The packing of the abdominal wound with gauze should be mentioned only to be condemned. It is not only unnecessary but decidedly harmful. It is a great source of irritation and discomfort to the patient. The pressure on the inflamed intestine may cause perforation, or intersusception. The theory upon which the wound is packed with gauze is: first, to prevent the pus from passing into and infecting the abdominal cavity; second to secure free drainage. Experience teaches us that the former condition is not secured; on the contrary the distention of the wound and separation of the parts is favorable to abdominal infection. The latter

Weighing in Tuberculosis.—Wolf-Immermann calls attention to the benefits to be derived from systematic, accurate weighing in the treatment of tuberculosis. He considers the scales as important as the thermometer. The average gain in weight in his sanitarium, Reiboldsgrün, is 360 grams a week, without over-feeding or remaining in bed. He advocates appropriate exercise.—*Munich Med. Woch.*, June 21 and 28.

condition—good drainage—is rendered difficult or impossible when the wound is pressed full of gauze. Leave the pus cavity and abdominal wound free from unnecessary interference, and nature will in a few hours shut off the septic region, by building a firm wall of protective adhesions around it. The healing process will not be delayed, and in a great percentage of the cases there will be no trouble from a future ventral hernia.

While it is hard to lay down any hard and fast rules, as the incision must conform to the particular conditions in each case, yet an operator has a characteristic method which he follows. The incision which combines conditions most favorable is a straight incision, not more than one and one-half inches in length, just external and parallel to the rectus muscles in the fibrous tissue of the linea semilunaris. In this location an easy and bloodless passage can be made to the cavity, and it is the only safe place one can be made in a pus case. The incision is closed in three layers: first, the deep aponeurosis and peritoneum are closed with a continuous catgut or kangaroo tendon suture; second the superficial fasciae are closed in a similar way. Third the skin is united with a number zero catgut suture. When thus properly united it gives a firm cicatrix and is not liable to give way.

I have had four cases of women who have borne children after an appendectomy without injury to the abdominal wall: two were operated upon during pregnancy. With the short incision the nerve-supply is not cut off from the abdominal muscles.

In pus cases, the incision is seldom more than an inch and a half. After the abscess is cleansed with pyrozone, and washed out with the saline solution, a wick drainage is placed in the lower angle of the incision and the wound is closed, except for the drainage. The wound is never packed with gauze, for reasons previously stated. The following case came into my hands for operation for the radical cure of ventral hernia following an operation for appendicitis:

M. R., a boy aged 4 years, was operated upon for suppurative appendicitis by Dr. S., July 17, 1895, at the Hartford Hospital. Later a fecal fistula occurred, for the closure of which four operations were performed, the last and successful one by Dr. Wiggin of New York. During the treatment a rubber drainage tube was lost in the cavity. The patient returned home Aug. 19, 1896. In December following, an abscess formed on his back just above the brim of the pelvis. Jan. 2, 1897, the abscess broke and discharged, and the rubber drainage tube was drawn out through the opening. He was taken to St. Francis Hospital in October, 1897, to be operated upon for ventral hernia, where the following measurements were made by Dr. Geo. C. Bailey: The opening in the abdominal wall was three inches wide and three and a half inches long. The prospect for a successful operation was so uncertain that the members of the surgical staff were opposed to having the operation performed in the hospital. The patient was taken to my private hospital, where the operation was performed Nov. 27, 1897.

An incision was made the entire length of the opening in the abdominal wall, adhesions were broken up so as to free the intestines from their attachment to the abdominal wall. The tissues were dissected back so as to expose the free border of the rectus muscle. Four silver wire sutures were inserted an inch from the free border of the incision. The mus-

cles were brought together by a continuous kangaroo tendon suture, passed through all the subcutaneous tissues, including the border of the rectus muscle, as they could not be separated, owing to the long-continued and inflammatory and suppurative process. The skin was then closed by a continuous kangaroo tendon. The silver wire sutures were drawn firmly together, so as to relieve the tension on the stitches through the muscles. At the end of one week the wire sutures at the end of the incision were removed, one of the remaining was removed in ten days and the last in two weeks. A liquid animal diet was given to prevent the distention of the abdomen until a good union had taken place. The patient made an excellent recovery. At the present time there is no sign of the return of the hernia.

As a result of tracing two hundred consecutive cases following appendectomy in reference to ventral hernia, while not absolutely complete yet nearly so, my statistics are as follows:

Class 1. Cases without extensive adhesions—infected exudate masses of pus, 52; hernia, 0.

Class 2. Cases with extensive adhesions—without infected exudate masses of pus, 54; hernia 0.

Class 3. Cases with infected exudate masses or pus, 48; hernia, 6.

Class 4. Cases with infected exudate masses and pus—with perforation and gangrene, 46; hernia 4.

Total number of cases 200; hernia 10, or 5 per cent.

CONCLUSIONS.

The factors in the production of hernia, following appendectomy, are, 1. Long incision. 2. Cutting off nerve supply to muscles. 3. Incision made through muscular tissue. 4. Closing the incision with a single set of sutures in one layer. 5. Packing the wound with gauze. 6. It is a question if the length of the incision is not more important than the tissues through which it is made.

ADRENAL TUMORS OF THE KIDNEY.

[ABSTRACT.]

Presented to the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY BAYARD HOLMES, M.D.

CHICAGO, ILL.

Grawitz first described a group of tumors of the kidney which resembled the adrenal tissue in histologic elements. He named these tumors or this condition *struma supra-renal is aberrata*, and from that time on a war has been waged over these forms under various names, all of which are more or less significant. We may say, however, that at present, a tumor of the kidney is recognized, growing out of remnants of the embryonal adrenal gland left behind in the kidney substance itself. Similar tumors are found throughout the whole genito-urinary tract. These tumors are sometimes malignant, but more often benign. They sometimes produce constitutional symptoms, but usually they come to the notice of the physician or surgeon solely on account of their size and location.

The case which I wish to present to you very imperfectly and briefly is an illustration of that form of adrenal tumor which produces on the one hand constitutional symptoms of a most marked character, and on the other hand, shows the malignancy of metastasis.

Mr John C., 56 years old, came into the care of

Dr. Edgar Hawley of Chicago in March, 1897. He had been a healthy, temperate man, and suffered no disease worthy of mention during his whole life. He had always led a moderate life, and been occupied most of the time in active office work, but during the past six or eight years has been confined for a reasonable number of hours each day to book-keeping. During the week preceding his illness he had lost in strength and appetite, but had slept well, complaining only of occasional loss of breath.

Dr. Hawley was called on the second day of the patient's absence from work. The patient was lying upon his right side; his breathing was rapid and he complained of excessive pain in the region of the right thorax. His pulse was slow, 72, and his temperature low, 99. He coughed frequently, and expectorated a bloody mucus resembling the rusty sputa of pneumonia. The patient's face was blanched, his lips red, but turgid, and an examination of the thorax revealed dulness over the whole lower half of the right lung, accompanied in places by complete absence of vocal transmission; while in other places, especially in the upper front part of the chest, there were many spots of bronchial breathing and crepitant râles. The area of cardiac dulness was greatly increased, and the area of hepatic dulness projected $2\frac{1}{2}$ to 4 centimeters below the border of the ribs. The patient's digestive functions were carefully examined without disclosing any significant fact. Urinalysis showed that it contained no abnormal constituent, except an increased quantity of indican and an increased quantity of all the normal constituents. The patient was able to rise and sit up to drink and for stool. Symptomatic treatment was instituted. On the third day of observation the pleuritic effusion was so great and the dyspnea so severe that Dr. Hawley removed three pints of bloody serum with the aspirator. The temperature remained about 99 and the pulse varied between 70 and 80. Two days later it was necessary to remove another quart of effusion, and a week after the beginning of treatment I was called in consultation on account of the gravity of the symptoms and the failure of the consolidated lung to show any symptoms of resolution.

When I saw the patient he was suffering from terrible dyspnea. His face was full, but blanched. His lips were a bright red. His eyes were bright and expressive. He seemed to weigh about a hundred and seventy pounds. There were no symptoms of emaciation. His hands were thin and white. His whole appearance reminded me of sclerosis of the kidney, and I instinctively uncovered his legs, expecting to find them greatly swollen with edema. I was surprised to find the legs and feet solid, but well-formed and excessively pale. The pulse at this time was hard and full, and very slow, 70 to the minute. The temperature was not quite 100, and it had never been above 100.5 at any time. My examination confirmed the examination of Dr. Hawley. There was a considerable effusion in the right pleural cavity, with a large mass of atelectatic tissue above it. The liver was depressed about 4 centimeters, but did not extend abnormally to the left. The heart's apex was $3\frac{1}{2}$ inches from the median line, but the area of cardiac dulness extended at least 2 cm. farther to the left and 3 cm. lower than normal. The heart's apex was readily recognized on account of the fierce stroke which it made on the wall of the thorax. A careful examination of the left lung detected bronchial breathing and cogwheel respiration in two or three places in the upper

lobe; but on account of frequent coughing, these observations were not considered significant. The patient frequently expectorated a tenacious mucus which was once in a while tinged with blood. No very satisfactory examination of the abdomen could be made, because the patient could not lie down on account of the dyspnea. I assisted Dr. Hawley to remove the effusion. We succeeded in aspirating three pints of bloody serum. The character of this effusion resembled that which I had observed in cancer of the lung. A microscopic examination of this serum did not reveal any bacteria, but showed the presence of red blood corpuscles, white blood corpuscles and a few epithelial cells of uncertain origin. The examination of the sputa did not disclose the presence of the pneumococcus. After the removal of the effusion, the liver came back to its normal position under the border of the ribs.

With the absence of the evidence of pneumonia, with the absence of cachexia, with the sudden onset of the disease and its rapid course, I was only able to make an unfavorable prognosis, leaving the diagnosis entirely to the postmortem. The subsequent course was similar to the preceding. The dyspnea continued, the pulse remained very slow and hard and full. The patient complained of no pain, and the temperature never rose above 100.5.

The postmortem was made three weeks after the beginning of the disease and twelve hours after death. It was made by Dr. Henry D. Galloway and Dr. Edgar Hawley in the presence of the house staff and nurses of the Baptist Hospital.

The body was that of a well-nourished man, apparently fifty years old. Postmortem rigidity had begun. There were no marks of swelling or edema and only a small puncture where the last aspiration had been made between the fifth and sixth ribs in the right axillary line. The right thorax was dull on percussion, the left resonant. On opening the right pleural cavity, a large quantity, probably a quart, of bloody serum without flakes or clots was removed. The right lung was a mass of solid tissue, which on section showed it was composed of light, reddish masses, contrasting sharply with the bluish-black and mottled appearance of the intervening edematous lung. These masses were hard and firm, and did not subside under pressure. They were of a uniform texture, and seemed to be the outgrowth of multiple centers. The left pleural cavity contained three or four ounces of clear serum. The left lung presented a normal, but highly pigmented appearance. The lymph glands at the root of the lung were filled apparently with years of accumulated coal dust. Three foci similar to those in the right lung, but no larger than hazel nuts, were found in the lower part of the upper lobe of the left lung. The pericardium was filled with six ounces of clear serum. The heart muscle was firm, and the ventricles contracted. The coronary arteries were markedly sclerotic. The valves of the heart were competent, but showed marked sclerosis, and in places calcification. The abdominal cavity was free from fluid. The liver and spleen were normal, excepting for a general arterio-sclerosis. The stomach and intestines presented no marked abnormality. The right kidney was of normal size and shape and position, and was connected with the bladder by a normal ureter. The right adrenal body was of normal size and shape and location. The left kidney was surmounted on its upper end by a firm, hard tumor,

the size and much the shape of a small clenched fist. Like the right kidney, it was surrounded with fat. On section the kidney itself seemed perfectly normal, except that it was encroached upon in its upper part by the tumor, but separated sharply from it by a wall of connective tissue. This kidney was connected with the bladder by a normal ureter, and there is no reason to believe it in anything but a healthy condition. The cut section of the tumor showed that it was composed of various nodules, the center of each of which was in a more or less advanced stage of apparently fatty degeneration. In a few places masses apparently of old extravasated blood were to be found. The growing portions of the tumor were nodules the size of peas, and at the periphery of the tumor. The blood supply of the tumor seemed to be rich, and on carefully dissecting up the renal vein, the tumor was found to have invaded it so as to actually hang into its caliber.

Microscopic examination of this tumor showed that it was a typical struma suprarenalis aberrata of Grawitz. Microscopic examination of the tumors found in the lungs showed that they were of the same character.

A study of the literature of this subject may be summarized in the following conclusions:

1. Remnants of the adrenal body are found in various parts of the genito-urinary tract in a large per cent. of all postmortems (90 per cent.)
2. The suprarenal capsule or adrenal body is a ductless gland essential to life. It secretes a substance which slows the pulse, contracts the capillaries, and removes the pigment from the skin. When it is destroyed or removed, the patient dies, or if partially destroyed, he takes on the condition recognized in Addison's disease. When the adrenal body is greatly increased in its function, the skin is blanched, the heart's action is increased in power, but slowed, and the capillaries are contracted, and the whole vascular system undergoes the degeneration of arterio-sclerosis.
3. About one-third of all the tumors of the kidney appearing in adult life are of adrenal origin, but only a small proportion of these show a tendency to metastasis, and these metastatic foci are usually confined to the lungs or to the bones, and only rarely are they found in both places.
4. A few of the adrenal tumors produce the symptoms of poisoning with the adrenal extract. The poisoning does not always seem to be proportionate to the size of the tumor.
5. The removal of the tumor before metastasis takes place results in subsidence of the symptoms of poisoning. The tumors may be removed without loss of kidney substance, or by a complete nephrectomy.

CLINICAL RESULTS OBTAINED BY THE USE OF MY INSTRUMENT FOR COL- LECTING THE URINE SEPAR- ATELY FROM THE TWO KIDNEYS.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY M. L. HARRIS, M.D.

PROFESSOR OF SURGERY CHICAGO POLICLINIC.
CHICAGO, ILL.

A description of my instrument for obtaining the urine separately from the two kidneys was published first in the JOURNAL OF THE AMERICAN MEDICAL

ASSOCIATION, Jan. 29, 1898, and again in *Medicine* in April, 1898. The object of the present paper is to present a few clinical facts obtained by the use of the instrument, which demonstrate its advantages, applicability and reliability.

Case 1.—Mrs. D., age 31 years. American, without particular hereditary tendency. Except for present trouble she has always been a strong, active, healthy woman. About four years ago she began to have pain in the lumbar region. The pain was dull and intermittent and increased by violent exercise such as dancing, driving or riding in the cars. The attacks of pain increased in frequency and severity and in a year or two the urine after exercise, particularly dancing, was very dark in color and there would be a desire to urinate frequently. Twice she had attacks of severe pain in the left lumbar region followed by the passage of a small calculus. The pain in the back became almost constant and she was obliged to discontinue all exercise on account of the great increase of pain and hematuria excited thereby. The urine contained blood almost constantly, although, except following exercise, it was so slight in amount as to require the microscope for its detection.

On Feb. 14, 1898, by means of my instrument I collected the urine separately from the two kidneys. An analysis of the urine thus collected is as follows:

	Right kidney.	Left kidney.
Amount collected in 20 minutes.	12 c.c.	10 c.c.
Color.	Clear amber.	Cloudy, very light brown.
Reaction.	Neutral.	Strongly acid.
Urea.	0.7 per cent.	1.2 per cent.
Albumin.	Slightest possible trace.	Small amount.
Microscope.	Negative.	Red blood cells abundant; numerous flat epithelial cells, singly and in masses of several hexagonal cells; few leucocytes.

This analysis pointed very conclusively to the left kidney as the seat of the trouble, and taken in connection with the history made a diagnosis of renal calculus certain. One very interesting point shown by the analysis is the marked difference in the reaction of the urine of the two kidneys secreted at the same time. That from the right side being *neutral* while that from the left side was *strongly acid*. As the reaction was taken at once before secondary changes could take place an interesting point is thus brought up, namely, to what extent local conditions within the kidney may influence the reaction of the urine. It may be mentioned here, as adding to the interest and importance of this point, that the calculus found in the left kidney was composed of almost pure uric acid. As the patient had received prolonged medical treatment without benefit surgical measures were decided upon and on March 8, 1898, an incision parallel with and one centimeter below the twelfth rib was made, exposing the left kidney, which was cleared of its surrounding fat. Nothing abnormal could be detected by sight or palpation of the kidney. The pelvis of the kidney was then opened by an incision along the convex border. In passing through the substance of the kidney a small abscess containing six to eight cubic centimeters of thin light brown pus, was evacuated. A calculus was found lodged in one of the calyces and removed. It was only with considerable difficulty that the calculus was found and removed even after the finger had free access to the pelvis. The pelvis of the kidney was washed with hot sterilized water, the kidney sutured with catgut and the incision closed in layers, except at the angle, where a small iodoform gauze packing extended down to the kidney. This was removed on the second day. Healing followed *per primam* with perfect recovery.

Case 2.—Mr. H., American, age 37 years, family history good, never had any illness prior to present trouble, except gonorrhea, which he had had several times. About two years ago, following shortly after an acute attack of gonorrhea he

had a severe illness, lasting about six weeks. It was attended by fever, pain in the right side of the abdomen and right lumbar region. During this illness there was a sudden discharge of a large quantity of pus with the urine. He has never been well since this acute attack although he has been around and able to do some work. He has suffered almost constantly from pain in the right lumbar region, frequent urination, which is better and worse at times, and occasionally has spells of fever with chills, sweats, etc. There is pus in the urine constantly. Is pale, anemic, considerably reduced in flesh, and quite weak. His temperature varies from 100 to 103.5 degrees F. He sleeps poorly and has frequent night sweats; appetite poor; no cough. He urinates frequently, without difficulty. The urine contains considerable pus, although he says it is now what he calls quite clear, not containing as much pus as it does at times. Upon examination a large, rather firm, quite fixed tumor is easily felt in the region of the right kidney. All other organs appear to be normal. A clinical diagnosis could be made of cystitis with pyonephrosis of right kidney, probably of gonorrheal origin.

The main questions to be determined were: Is the left kidney already involved, and is it able to do the work alone, provided the right kidney be removed? To determine these points, on Feb 19, 1898, I collected the urine with my instrument. Owing to the presence of the cystitis, the bladder was thoroughly irrigated with sterilized water after the instrument was introduced and fixed in position. The urine all came from the left side, not a drop was found to come from the right kidney. The analysis of the urine thus obtained showed: amount in twenty minutes 14 c.c.; perfectly clear, dark amber, acid; urea 2.3 per cent.; albumin, very slight trace; very few flat epithelial cells, scattering leucocytes and a few cylindroids. The value and efficiency of the instrument are clearly demonstrated in this case.

Notwithstanding the existence of cystitis and a large amount of pus in the urine, we were enabled by the instrument to attain perfectly clear, practically normal urine from the left kidney. It demonstrated to us that the left kidney was normal and that it was doing all of the work. The amount collected, 14 c.c. in twenty minutes, is equivalent to 1008 c.c. in twenty-four hours. By actual measurement the amount passed in twenty-four hours was 1057 c.c. This again shows that the left kidney was doing all the work, and demonstrates how perfectly the septum is formed by the instrument in the bladder. It being satisfactorily shown that the left kidney was normal and able to carry on the work alone the patient was operated on Feb. 21, 1898. A long oblique incision was made beginning near the outer end of the twelfth rib and extending downward and forward internal to the anterior superior spine of the ileum. The kidney was found embedded in an immense mass of thickened, firm, connective and adipose tissue containing numerous foci of suppuration. One large perinephritic abscess containing from 100 to 200 c.c. of thick yellow pus was evacuated. It lay between the superior pole of the kidney and the inferior surface of the liver. The kidney was found to be a mass of innumerable small abscesses. There was no dilatation of the pelvis. The whole kidney was so involved in a dense connective tissue mass that no pedicle composing the vessels for ligation could be formed. Two large angular clamps were therefore applied to grasp the renal vessels, and the kidney with considerable of the connective adipose mass removed. The clamps were left in place and the wound packed with plain sterilized gauze. Considerable shock followed the operation and for forty-eight hours the patient was quite low. At the end of this time the clamps were removed. He

now began to improve rapidly, temperature became normal, and he left the hospital March 12, less than three weeks from the date of operation, with the wound almost healed. The cystitis improved remarkably, the urine, which he was passing freely, contained but very little pus when he was discharged.

Inoculations made from the perinephritic abscess on blood serum agar developed a diplococcus resembling the gonococcus, which died out in the second generation. The kidney upon examination was found to be tuberculous and the secreting portion practically destroyed.

Case 3.—Mrs. S., age 39 years, American, has been suffering many years with what was supposed to be cystitis. She had painful and frequent urination with pyuria, the frequency becoming so great that she was obliged to wear a urinal constantly. She also suffered with a burning pain in the sacral region, which frequently extended into the thighs. She had some pain in the lumbar region, which was always referred to the left side and no pain on the right side. She was treated for years for bladder trouble, receiving all manner of irrigations, local application, etc., without benefit. She then came into Dr. J. Frank's hands, who, upon cystoscopic examination, decided for the first time that her trouble was not located in the bladder. Dr. Frank tried cauterization of the ureters, after Kelly's method, and, although he succeeded repeatedly in catheterizing the left side could never succeed on the right side. There was no tumor to be felt in the region of the kidney on either side, but some pain was always referred to the left side. Through the kindness of Dr. Frank I was asked to examine her with my instrument. This was done, March 10, 1898, with the following result:

	Right.	Left.
Amount collected in 20 minutes.	8 c.c.	10 c.c.
Color	Pale, milky, cloudy.	Clear, light amber.
Reaction	Neutral.	Acid.
Urea	0.05 per cent.	1.05 per cent.
Albumin	Well marked quantity.	Small amount.
Microscopic	Pus-scattered cells and in large clumps or masses. Few red blood cells.	Few flat cells and an occasional leucocyte.

No bacteriologic examination was made.

The examination demonstrated conclusively that the disease was located in the kidney and in the right one alone; the left kidney was secreting practically normal, healthy urine notwithstanding the fact that the pain had always been referred to the left side. The character of the fluid obtained from the right side, thin, purulent, albuminous, neutral, 0.05 per cent. urea, showed that the secreting portion of the kidneys must be almost entirely destroyed with little else than a pyocystic condition remaining.

Upon the results of this examination Dr. Frank removed the right kidney March 19, 1898. He found the kidney practically destroyed, nothing but a multiple, cystic, purulent, tuberculous mass remaining. The ureter was much thickened and dilated. The patient recovered. This case illustrates a very important point which has been observed before, namely, the pain is not always referred to the diseased side. This patient never complained of pain in the right kidney, the diseased one, but always in the left kidney, the apparently healthy one.

Case 4.—Mr. S., age 30 years, decorator, good family history, never seriously ill and no sequelae to the usual diseases of childhood. States he had a serious and continuous hematuria eight years ago, which persisted for eighteen months, then ceased. Four years ago he had a severe fall on the walk, but noticed no trouble from it. Two years since he again noticed the hematuria for which he consulted an eminent specialist who made a cystoscopic examination, thought he saw a papilloma of the bladder and advised exploration. The patient drifted away and after two years consulted Dr. Whitfield who referred him to Dr. L. L. McArthur for diagnosis.

Examination revealed a somewhat anemic condition of a

young man of good physical development without a subjective complaint. Blood examination showed lowered blood count, relative proportion normal. No plasmodium. The urine was constantly bloody, although the amount of blood present varied somewhat from time to time. It was always intimately mixed and unaccompanied by clots of any dimension. The amount of urine in twenty-four hours was 543, sp. gr. 1020, and albumin; no sugar; no pus. Microscopic examination showed no elements except the blood and an occasional blood cast.

Through the kindness of Dr. McArthur, I had an opportunity to use my instrument on the patient. The result was most satisfactory and very striking. The urine from the right kidney was perfectly clear, and normal in every respect while that from the left kidney contained all of the blood, demonstrating absolutely the left kidney as the source of the hematuria.

These four cases are by no means all that have been examined as I have made now some forty examinations. Each of the four cases mentioned, however, illustrates some particular point and taken together they demonstrate the wide range of applicability of the instrument.

Case 4 is an absolute demonstration of the completeness and perfectness of the septum or watershed formed in the bladder. A more beautiful demonstration could scarcely be imagined; in one vial the red, bloody urine, while in the other perfectly clear, normal urine.

Case 2 demonstrates the fact that clear normal urine can be obtained from the kidney notwithstanding the presence of a purulent cystitis.

In Case 3 the use of the instrument led at once to a correct localization of the disease and the side involved, when the symptoms all pointed to the opposite side as the one probably diseased. This much for the clinical aspect of the subject. Concerning the mechanical use of the instrument it may be said that this is not difficult. A few simple rules that have been sufficiently detailed elsewhere are all that are necessary to follow. Most of these are such as would naturally suggest themselves to any intelligent physician attempting to use such an instrument. Some may appear trivial but all of them have been found by actual experience to be necessary in order to guard against a possible error or to facilitate the use of the instrument. By following these simple rules I feel certain the results will be most gratifying and the necessity of laying both kidneys free on the back to determine the presence and extent of disease in them as recently recommended by Edebohls (*Annals of Surg.*, 1898, xxvii, 425) will no longer exist.

DISCUSSION.

Dr. McARTHUR of Chicago—I have used this instrument and bear willing testimony to the excellent results. Very few of us who have attempted ureteral catheterization have done so without experiencing great difficulty, but it is now easy to obtain the urine in two separate bottles, and I have been charmed with the result. Take the case of a man who has passed bloody urine for years without any symptoms clinically or any evidence microscopically of a disease, and you have a case that will at first puzzle you. In such a case, to have two bottles of urine side by side will convince you that the blood is coming from above, and that the trouble is in the kidneys. In the same way an enormous tumor of the right side, which needs to be diagnosed from a cyst of the gall-bladder or a cystic kidney of the right side, will be proven—although previous examination of the urine has shown nothing of interest—to be a cystic kidney, and not a cyst of the gall-bladder, by the total absence of any urine from that side. An incision can be made and the diagnosis confirmed.

INJURY TO PERIPHERAL NERVES AND THEIR SURGICAL TREATMENT.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY A. H. LEVINGS, M.D.

MILWAUKEE.

It may be stated without fear of successful contradiction that the subject of injury to peripheral nerves is one which has not received any very extensive consideration from surgeons. It is indeed true that the frequency of nerve injury is not great when compared with injury to bone, muscle, artery or vein, but when such an injury does occur, especially if to a principal nerve, the importance of the injury is unquestioned. If a motor nerve be divided, its function throughout the area of its distribution is at once arrested, and this loss of function, excepting some slight restoration which may come from anastomosing branches, remains until the continuity of the nerve fibers has been re-established.

The opinion almost universally held by pathologists and surgeons is that certain characteristic changes occur in a peripheral nerve after division, these changes being more pronounced in the terminal than in the central portion of the divided nerve. The changes consist in the breaking up of the medullary sheath into fat drops, and their absorption with a disappearance of the axis cylinder, the neurilemma sheaths alone remaining. It is also generally accepted that following the section of a nerve, if it be properly sutured, regeneration commences in the central end by a splitting up and growth of the axis cylinders which are projected to and through the neurilemma sheaths to the very peripheral portion of the nerve; following this medullary sheaths are formed around the axis cylinders. Some hold that regeneration is effected through the nuclei of the neurilemma.

It was for the purpose of determining, as far as possible the extent of nerve degeneration after section, and the manner of the regenerative changes, as well as the best method of surgical procedure in divided nerves, that I undertook a large number of experiments upon the sciatic nerve of different animals. Eighty-five sections of the sciatic were made, and seventy specimens were taken and examined, both macroscopically and microscopically. So far as my experimental work goes it seems to demonstrate that the presence or absence of degenerative changes in a divided nerve depends very largely upon the treatment instituted, and also, to some extent, upon the state of health of the animal operated upon.

If a divided nerve be immediately sutured, or if a gap caused by resection be immediately bridged with some suitable material, and the work be done aseptically and properly, but slight degenerative changes will take place either in the distal or proximal portion of the nerve; and the nerve's function will, in the great majority of cases, be quickly re-established.

On the other hand, if the nerve ends be not approximated, if an interval caused by resection be not bridged, or if suppuration occur in the wound, then pronounced degenerative changes will occur in the nerve, more especially in the terminal portion, and a restoration of function will not occur. In opposition to the oft-repeated statement that "a divided nerve will first degenerate throughout its entire peripheral extent, and be absorbed and following this, regenera-

tion will take place through a branching and shooting of the axis cylinders before function can be restored," stands the clinical fact so often observed, that after section of a nerve and immediate suture, function, both motor and sensory, has been established in a few hours or days, confessedly too soon for the complicated process of degeneration to have occurred.

Neither in analogy nor in physiology am I aware that there is anything which would bear out such a statement. It is supposed by Howell and Huber that in the normal nerve fiber the nutrition of each internode is directly controlled by the internodal nucleus; and that the metabolic activity of the nucleus in turn is influenced by trophic impulses received through the axis cylinder from the nerve centers. When the flow of these impulses is interrupted, the metabolisms of the nucleus and its dependent structures, myelin and internodal protoplasm, are altered, and the degenerative changes in the myelin and axis cylinders take place. After division of a nerve, anything which connects the two ends, whether it be by immediate suture or by filling up a gap between the separated ends with some suitable material, seems to render possible the continuance of these trophic impulses to the peripheral portion of the nerve; thereby sustaining metabolic activity, preventing degenerative changes and favoring repair and the early restoration of function.

An examination of my specimens convinces me that the neurilemma with its nuclei plays an important part in the restoration of a divided nerve. If a longitudinal section of a nerve be examined shortly after function has been restored, one will find at some distance from the place of union the nerve fiber in a normal condition. As one approaches the line of union the nerve fibers grow smaller, thinner and fewer, and when at the line of junction there will be seen a leash of fine neurilemma strands crossing the field and coming from both directions. Some of the fibers have a medullary sheath, while the major part have none. Both the central and distal portions of the nerve seem to take an active part in the projection of the neurilemma threads across the line of section.

Essentials to a successful operation.—1, absolute asepsis, for without this we cannot hope to succeed; 2, the nerve should not be separated from its connective tissue surroundings; 3, the nerve ends should be approximated squarely and evenly, and without tension; 4, if an inch or more of the continuity of a nerve be lost the gap should be bridged with some material having longitudinal strands or fibers; 5, contrary to the common belief, absolute rest of the limb is not an essential to success. The methods of operating may be divided into immediate suture, bridging a gap and secondary suture. A divided nerve should be united at the earliest possible moment, as this will lessen degenerative changes and will favor the early restoration of function. Where there has been a simple section of the nerve, or a resection of less than an inch, the nerve ends may be approximated by slight stretching and held by two sutures placed at right angles to each other; the nerve ends should be allowed to just touch each other. If the stitches are drawn tighter than this, the nerve fibers will be bent at a considerable angle near the ends, and the restoration of function will be much hindered.

Restoration of function.—In nine resections of the sciatic of less than an inch, and in thirteen sections with immediate suture, function was restored in one case

in five days, in one in nine, in two in ten, and in one each in thirteen, seventeen and twenty-six days respectively. Three of the animals died, and of the remainder function was imperfect at the end of thirty days. The results in a few are not stated. The success of the operation depends very much upon the technique; and in dogs upon their condition. Operations done upon unhealthy dogs, or during the summer when they may be pestered with flies or fleas, give poor results.

Filling a gap.—In cases where an inch or more of the continuity of the nerve has been lost, one of several methods may be resorted to for the purpose of supplying the deficiency. The nerve may often be stretched sufficiently to approximate its ends. Forcible stretching of a nerve in order to approximate its ends has not, in my experience, been productive of good results, and I do not believe it is desirable. Forcible stretching produces degeneration and favors paralysis. Splitting of one or both ends of the nerve and turning a flap or flaps, has been and is practiced. This method does great injury to the nerve and has nothing to recommend it. The flap does not remain as a vitalized part of the nerve, but simply acts as a bridge through which the nerve fiber must grow, and the bridge is badly situated for the purpose. The flap method was practiced three times in my experiments; in one case some slight restoration of function made its appearance upon the fifteenth day. There had been in this case resection of one inch of nerve. The other two experiments were failures.

Bridging the gap with a piece of nerve taken from another animal is an excellent method, and has but one objection; the technique is complicated, requiring an animal and two operations instead of one. In a dog, after resection of one inch of the sciatic, I introduced a like piece of the sciatic from a rabbit. After fifty days there was no return of function; but of course this single experiment proves nothing. In three instances I brought the ends of the resected nerve inside of a piece of decalcified bone, running threads from one end of the nerve to the other. The results in these experiments were not as successful as by some other methods.

Bridging the gap with silk threads.—Auger, Assaky and Glück had used this method for bridging gaps in tendons, and Assaky applied it to bridge defects in nerves, using catgut. Abundant experience has shown that when a portion of nerve up to three inches has been resected and the gap filled with some suitable material having longitudinal fibers or strands, and thus indirectly connecting the nerve ends, this bridge will act as a scaffolding through and upon which nerve fibers will be projected, filling the gap and re-establishing the nerve function. Experience has shown that silk strands, preferably six in number, stretched from one end of the nerve to the other, act as such a scaffolding and fulfill the indication extremely well. Seven experiments were made with the silk bridge, having resected from one to two and one-half inches of the nerve. In one case function was restored in twelve days, in others in twenty-one, twenty-two, twenty-five and forty-six days, respectively; one animal escaped, and of one there is no record.

Bridging the gap with muscle.—While making these experiments it occurred to me that a piece of the adjacent muscle might be used to advantage to fill the gap, as it was always at hand, was porous, and had

longitudinal fibers, and having the additional advantage of affording a vitalized bridge. Thirty-eight experiments were made with a bridge of muscle. In my earlier experiments the small piece of muscle was detached entire with its fascia. In the latter experiments, the piece was detached only at the ends, leaving it connected in the middle and thus insuring the continuance of its vitality, and giving more uniform and better results. In these experiments the extent of nerve resected varied from one to three inches. In two cases function was restored in 10 days, and in others in 12, 17, 22, 26, 28, 29, 30, 31, 35, 40, 42, 50, 51, 52, 75, 90 days, respectively. Some of these operations were secondary. In one case, after resection and prevention of union, the bulbs were after a few weeks resected and a three-inch piece of muscle introduced. Function was restored in forty-two days.

I am able to report the following case in which a secondary operation was done and pieces of muscle were used to bridge the gaps: Mr. J. B., aged 46, consulted me in January last on account of an injury which he had received in 1869 by falling upon a sharp scythe and cutting the ulna and median nerves in his right wrist. In the closing of the wound no attempt was made to unite the nerves, and there occurred at once complete loss of sensation in the area and paralysis of the muscles supplied by these nerves beyond the site of division. At the time the patient presented himself to me there was partial restoration of sensation in the hand, but paralysis was still complete with great muscular wasting. On February 5 I cut down upon the nerves and resected the bulbs. In the case of the median these were indirectly connected by a band of connective tissue. There was absolutely no connection between the bulbs on the ulnar. There was a gap of more than an inch in the ulnar and of three inches in the median. These gaps were bridged with pieces of muscle taken from the superficial flexors. After the operation there was absolute loss of sensation in the hand. In six weeks sensation was fairly well restored excepting in the terminal phalanges; and now after four months, sensation is almost normal. Muscular function has not up to the present time been much improved, although there is a seeming gain, especially in size and control of the muscles of the little finger, and to some very slight extent, also, in the thumb.

I would submit the following conclusions:

1. That immediate suture, or immediately filling a gap after resection, prevents marked degenerative changes in a nerve.
2. In gaps of one inch or more it is preferable to put in a bridge rather than approximate the nerve ends by stretching.
3. That the new nerve fibers are formed by the nuclei of the neurilemma, and that both the terminal and the central ends take a prominent part.
4. That the operation, to succeed, must be done aseptically.
5. That in approximating the nerve ends, or putting in a bridge, the sutures must only allow the abutting ends to touch.
6. That for the purpose of filling a gap there is no material in use at the present time which compares with muscle.

DISCUSSION.

Dr. CHARLES A. POWERS of Denver—I would like to relate a case which occurred in my own practice, of a somewhat similar nature. It was the result of a railroad accident causing a lac-

eration of the external popliteal nerve. The wound was cleaned out and in six weeks I united the ends of the nerve by bridging with a piece from the sciatic nerve of a dog. Before uniting the ends were about four inches apart. I used fine black silk thread, passing it merely through the sheath of the nerve, simply allowing the cut ends to come in contact, and the wound healed by first intention. Sensation began to return on the sixth day and was complete in four weeks, but function has never returned. As to the choice of material to employ in bridging a nerve, I think, perhaps nerve tissue itself is as good as anything. Dr. Levings seems to have gotten excellent results from muscle tissue, but both are easy to get.

Dr. R. H. REED of Rock Springs, Mont.—The question is one of great interest to all of us, as we are constantly coming in contact with emergency work of this kind and it is necessary for us to give our patients the best possible results. If the function of the nerve is destroyed and the ends can not be brought together, the distance being so great that bridging would be of considerable length, it is often necessary to find some other method of restoration. It has been shown that the proximal end of the nerve is the one where regeneration commences, which is modified by the amount of nutrition at the distal end. By using neural infixation in the way I illustrate on the blackboard, the function of the injured nerve is readily restored. Galbraith first demonstrated this in a case of injury to the musculo spiral nerve, and I have secured very good results in a number of cases where I have employed it, motion and sensation being restored. As to the time being several months before regeneration takes place, this is a mistake, as in several cases in which infixation has been employed, the function of the nerve has been restored in ten days. I have seen it show itself in five days, and in thirty days the use of the arm has been complete.

Dr. LEVINGS, in closing—As to Dr. Powers' case, in which sensation was restored but not function, this is often the case and has occurred in my own practice, I believe, owing to an anastomosis of collateral branches. Concerning the material to be used, I believe silk is the best. I have employed catgut, but it fails. As to the bridging of a nerve, there is nothing that can be said against it except that it requires an animal and two operations. The nerve does not retain its vitality as a nerve, but simply as a scaffolding. It used to be thought the two ends of the nerve were healed and the integrity of the axis cylinder retained, but this is incorrect. I seldom make a bridge of more than three or four inches in length. Dr. Reed's method is one that is well recognized and it is all right where it can be accomplished, but the nerves are often widely separated. In a case where the ulna and median have been divided, you only have the radial left, so that the method could not be employed under such circumstances.

SURGICAL TREATMENT OF PERITONEAL TUBERCULOSIS.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY BYRON B. DAVIS, M.D.

OMAHA, NEB.

With one exception the recent writers I have consulted are in full accord in the assertion that laparotomy is a potential factor in the cure of peritoneal tuberculosis. Curtis (Twentieth Century Practice, Vol. viii), says that he is of the opinion that the disease is not so fatal after all has been supposed, and that many of the cases of recovery after laparotomy are instances of spontaneous involution. On the other hand, from Koenig, who in 1884, first brought this mode of treatment forward and proposed it as a formal measure, reporting three cases cured, to the latest writer on the subject, most of those who have had experience with the method have been in accord in asserting its value. The early dissenters from Koenig's doctrine were men who had not tried the treatment. A few trials usually convinced the most skeptical. The percentage of cases cured by laparotomy is variously stated at from 35 to 80 per cent. The former figure is probably too small and the latter too large. Unfortunately there seems to have been

very little account taken of the stage of the disease at which operative interference was undertaken, or of the organs, other than the peritoneum, involved.

Though in the majority of instances simple incision through the abdominal wall has been sufficient to produce the desired result, there are frequent cases in which more than this must be done if the best results are to follow. If, for instance, tuberculosis of the tubes or ovaries antedates the peritoneal infection, permanent cure following simple abdominal incision could not be counted upon with any degree of certainty. Temporarily the desired object might be obtained, but with a tube or ovary centrally diseased, a second infection of the peritoneum would be imminent. In such a case the operator serves his patient best if he removes the tube and ovary in order to guard the peritoneum against a reinfection. In the same way, if a tuberculosis of the intestines, of the appendix or of the mesenteric glands is the source of the peritoneal infection, and the disease at the original focus is still active, to expect permanent immunity—the primary focus being untouched—would be scarcely reasonable. The omission of the removal of the primary focus of the disease is undoubtedly frequent, and it is also believed that late relapses—really new infections from the original source—are much more numerous than is generally supposed. The late relapse is a proof of the incompleteness of the operation.

An operation may be incomplete because the operator fails to recognize the primary focus of the disease; because such focus cannot be removed without too great risk to the life of the patient, or because the operator fails to recognize the menace of a second infection. So important do I consider this, that it is my practice, when not readily apparent, to make a careful search among the abdominal viscera when operating for this disease, in order to find and remove everything which seems suspicious or threatening. The only contra-indication to the removal of the primary focus is when it cannot be done without too great risk to the immediate life of the patient. The question of how extensively to remove the diseased tissue must be decided on the merits of each individual case. In deciding how much the patient can safely endure, the surgical judgment of the experienced operator will seldom lead him astray. If no primary focus of disease is found, we are to conclude that it is so slight that it has been overlooked, that the disease originated from a distant part of the body, that it is of the so-called hematogenous type of infection, or that the primary source of infection has undergone spontaneous involution.

Shall we irrigate or not irrigate? The question of irrigation may safely be left to the taste, choice or habit of the operator. Unless there is found in an individual case a special reason for irrigation, as broken down caseous masses, pus or flocculent serum, nothing is to be gained by the use of irrigation. In 308 cases collected by Aldibert the most favorable results were found among those in which the abdomen was merely opened. Perhaps a tendency to irrigate the worst cases, and to omit the measure in the less severe, will account for this discrepancy.

Shall drainage be used or primary suture be employed? For reasons which I hope to make plain when speaking of the manner in which the cure is produced, it is my opinion that drainage is a real detriment to cure, and that where it is safe to omit

drainage and close the wound at once the best results will be secured.

The question of the breaking up of adhesions is also one to which it is not best to attach any hard and fast rules. If old and firm and extensive, little will be gained and much risk will be run, if one is too diligent in this direction. The fact that new adhesions will almost immediately form, that the integrity of the bowel is likely to be compromised, and the additional shock which too much energy in this direction entails, all speak for conservatism in dealing with adhesions. The curative ratio is fully as high, as far as it has been possible to ascertain the results, where dense adhesions have been allowed to remain. On the other hand, if any adhesions threaten to produce intestinal obstruction by causing augulation or constriction, if they are new and easily separated, or if they prevent access to a supposed primary focus which it is desired to remove, they should be carefully separated.

Why does the performance of abdominal section cure these cases? This question is approached with a great deal of hesitation. That it does cure is abundantly proven by hundreds of recorded cases. A recent experience in two cases, in which I had the privilege of doing secondary laparotomy for other purposes, and in which I found perfect cure of the peritoneal tuberculosis, has brought this subject before me with renewed interest. A variety of ingenious theories have been brought forward, most of them entirely unsatisfactory, a few which look reasonable. In order to study the phenomenon advantageously it may be well to consider the histological changes which occur in the tubercle during the process of healing. Recall for a moment the histological elements of the tubercle. First, there is an accumulation of round cells (lymphocytes) about the group of vessels at the point of infection; next, some of the round cells in the center of this mass are transformed into epithelioid cells rich in protoplasm; multiplication and growth of same; one or two giant cells formed by nuclear proliferation of epithelioid cells; the next step is the formation of the connective tissue framework; tubercle bacilli are also present. In the young tubercle the round cells predominate; then the epithelioid cells gain the ascendancy, these last slowly enlarging by the swelling of their protoplasm. In the completed tubercle the connective tissue takes a concentric form at the periphery; it is sometimes very delicate, scarcely perceptible, sometimes strongly developed, forming a sort of capsule for the tubercle, and is endowed with fibro-blasts. In the center of the tubercle the connective tissue forms a very delicate stroma. Only very seldom is the central framework strongly pronounced, and in old tubercles it is scarcely perceptible between the closely packed epithelioid cells. Later in the history of the tubercles caseation occurs in the center, and then the connective tissue framework at the center disappears. Gatti of Turin, to whom I am indebted for much of the material used in the preparation of this paper, has carefully studied the development and decadence of the tubercle, and divides its life into three stages:

1. The fibrous stage, which includes histologically the miliary tubercle, the diffuse and the first beginning of the nodular form.

2. The mixed fibrous and caseous stage (*præcaseous*), which makes the transformation from the fibrous to the caseous tubercle.

3. The caseous stage, after this transformation has been completed.

Having in mind now the specific elements of the developed tubercle, an effort will be made to trace its involution after a curative laparotomy. It is to be noted that it has been proven by Gatti's numerous experiments upon guinea pigs, rabbits and dogs, that if the operation is performed before the fibrous tubercle has reached its full development it is without effect.

To Osler seems to be due the credit of making the first histologic study of the process of healing after an abdominal incision. He found fibrous tissue holding in its meshes a few giant cells and isolated tubercle bacilli.

Pichini made a microscopic study of peritoneal tissue from a cured case, and concluded that after operation the tubercle underwent a connective tissue transformation.

Riva also found a growth of connective tissue, but observed that the process of transformation, instead of advancing from the periphery toward the center, had its beginning in the center of the tubercle.

Kischewsky, who was the first to experiment with the lower animals, concluded that the disappearance of the tubercle was due to leucocytic infiltration, followed by an active development of connective tissue. Up to this time, 1894, observers had been in accord in the belief that healing of the peritoneal tubercle is due to a fibrous transformation of the cellular elements to sclerosis. The most noteworthy work in opposition to this teaching is that of Gatti, of Turin, who in March, 1894, and again in March, 1896, reported the results of carefully conducted experiments upon animals. The abdominal sections were made at all stages, from a few days to many months after the inoculation. The tubercles, in process of healing, were examined at every stage from twenty-four hours after the operation until complete repair had occurred. A brief abstract of Gatti's findings will be of interest: During the first week after the operation an amount of reddish serous fluid exudes into the free peritoneal cavity and gradually diminishes in quantity from the first to the seventh day. The first to third days showed the peritoneum slightly reddened; the third to seventh days showed the tuberculous tissue slightly increased in volume. The vascular congestion was very slight and restricted to the periphery of the tubercles and to the normal peritoneum between them. The connective tissue showed no changes, its cellular elements being in the same ratio as before, and above all there was no proliferation of the fibro-blasts. The round cells were neither more numerous nor changed in appearance. The epithelioid cells appeared unchanged and the phagocytosis was no greater than before. Twelve days after the operation beginning hydropic degeneration of the epithelioid cells was observed, drops and rings of fluid occurring in the cells. The entire protoplasm was here and there changed into a fluid containing the floating nucleus. No increase of the fibro-blasts was present. The tubercle bacilli were somewhat more numerous; phagocytosis was not increased. Gatti further asserts that connective tissue proliferation after laparotomy seldom occurs, and only to a limited extent, and that it is not occasioned by the operation. "In general," he says, "it may be absolutely observed that the increase of the stroma goes hand in hand with the development of the tubercle. If the tubercle is really influ-

enced by the laparotomy, and the specific irritation which has occasioned the development of the epithelioid, lymphoid, endothelial and connective tissue cells is arrested or diminished, so is the further growth of all these kinds of cells at the same time checked."

Continuing the description of the involution of the tubercle Gatti shows that, as the epithelioid cells degenerate and the fluid is absorbed, vacuoles are formed and the surrounding zone of connective tissue simply presses in to fill the space occupied by the vacuoles. Where the tubercles were already rich in connective tissue before the operation, this will be present in tolerable abundance in advanced healing; but it is only the connective tissue already existing before the process of repair began.

By the time the epithelioid cells have undergone hydropic degeneration all tubercle bacilli have disappeared from the tubercle. The reparative stages in the caseous tubercle are much the same except that the caseous masses are not absorbed, they being merely surrounded by connective tissue capsules. Cure by operation in this stage is less sure than before caseation has occurred. But even when healing does not follow, the development of the disease is usually slowed or completely checked.

The conclusion is reached that healing is not brought about by connective tissue growth, and that this error was made by the examination of cases that had fully healed. Connective tissue masses were found and the conclusion formed that healing occurred by pressure upon the specific elements of the tubercle by proliferating connective tissue. Only by examining animals at all stages after the operation can the process of healing be correctly studied.

Mazzoni asserts that the healing process consists partly of increase of connective tissue and partly of a cystic degeneration. This cystic degeneration doubtless corresponds to Gatti's vacuolization due to hydropic degeneration of the epithelioid cells.

I would suggest that it is probable that tubercles can heal by either of the processes given, depending upon what force is acting, to produce disappearance of the tubercle. If the process is set up by causes extrinsic to the tubercle itself, as by an improvement of the nutrition of the patient, causing greater powers of resistance to the inroads of the disease; in other words, if the protective power of nature to wall off against danger asserts itself, as occurs in spontaneous healing, the histologic process is probably a connective tissue proliferation, with pressure upon the central specific elements of the tubercle, causing their degeneration and absorption.

If, on the other hand, the force at work is intrinsic, something that destroys the activity of the tubercle bacilli, the process would probably be a degeneration of the epithelioid cells, the consequent formation of vacuoles, and the collapse of the enveloping tissue. A moment can now be profitably given to speculation upon the force at work which brings about the healing of a peritoneal tuberculosis after an abdominal incision. Many theories have been exploited, but time does not permit even mention of all of them.

Nannotti and Baciocchi think that the operation sets up an inflammatory reaction of the peritoneum, accompanied by a noteworthy increase of its absorbing power, phagocytosis, degeneration of the cellular elements, connective tissue growth and vascularization of the tuberculous nodules, with successive fibrous transformation.

Stechegoleff attributes the curative effect of a laparotomy to a combination of traumatism of the peritoneum, thermic influence, penetration of air into the abdominal cavity, and perhaps the action of light, causing irritation followed by an inflammatory deposit.

R. T. Morris of New York concludes from experiments, that recovery after operation occurs because putrefactive bacteria produce a toxalbumen in the peritoneal fluid which is fatal to tubercle bacilli in the peritoneum. The reason it is more effective in tuberculosis of the peritoneum than in the knee-joint and elsewhere is because of the exceeding abundance of the lymphatics in the peritoneum, bringing toxic agents, which are absorbed, into close contact with the bacilli.

The theory formulated by Gatti is that the serum of the blood of a person suffering from peritoneal tuberculosis is a true antitoxin. The serum which pours into the peritoneal cavity after laparotomy comes into close contact for several days with the tubercles, destroys or inhibits the tubercle bacilli and thus is set up the chain of events which leads to complete healing.

If Gatti's description of the process of involution of the tubercle is the correct one, his theory seems the more reasonable. How much antitoxic power the serum of the blood of a person suffering with tuberculosis possesses I am not in a position to determine. Granted that it does possess potent antitoxic powers, its presence in the peritoneal cavity and its absorption by the lymphatics bringing it into intimate contact with the tubercle bacilli, would seem to explain very fully the curative effects of laparotomy.

The fact that cure does not occur if the laparotomy is done very early, before the completed fibrous tubercles have formed, Gatti attempts to explain by the fact that in the formative stage the tubercle bacilli are more resistant than they are later. I would suggest that it can very reasonably be supposed to be due to the fact that up to that time the antitoxic serum has not yet attained sufficient potency to be effective.

The fact that, in cases in which drainage is used the results are less favorable, is understood, if the cure is due to an antitoxin, for, with drainage, the antitoxin is drained away instead of being absorbed by the lymphatics of the peritoneum. The increased amount of serum thrown into the peritoneal cavity, with the greatly stimulated powers of absorption which a laparotomy produces, would cause a very large quantity of antitoxin to be brought rapidly into intimate relationship with the tubercle bacilli, causing their destruction.

In conclusion, although I do not for a moment claim that Gatti's hypothesis has been proven, it has been brought forward because it seems rational, and because it does not seem as if his work has received the recognition it deserves.

TREATMENT OF PURULENT TUBERCULAR PERITONITIS BY INCISION, WITH AN ILLUSTRATIVE CASE.

Presented to the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY ROBERT REYBURN, A.M., M.D.

WASHINGTON, D. C.

Modern aseptic surgery has of late years achieved many magnificent results, but in no field have these

successes been so striking and wonderful as in that of abdominal surgery.

Among the later and by no means the least important of the triumphs of abdominal surgery, is the treatment of purulent tubercular peritonitis by free incision into the abdominal cavity, with thorough evacuation of all pus or septic material. Tubercular peritonitis we believe to be always a secondary infection from the tubercular bacillus, which has obtained entrance into the system, either through the digestive or respiratory organs. The following case, which recently came under the observation of the writer, is herewith given.

Was called in consultation with Dr. Wilder on Feb. 28, 1898, to see E. S. K.; mulatto; aged about 14 years. He was fairly well nourished and weighed about 110 pounds. He gave a history of exposure to inclement weather some ten days before I saw him, which was followed by symptoms of peritonitis. For four or five days he had suffered from irregular hectic fever, temperature ranging from 100 degrees to 102 degrees. On examination his abdomen was found enormously swollen, tense, and dull on percussion, and evidently filled with a large amount of purulent material. Operation by incision was advised and somewhat reluctantly acceded to. March 2, 1898, an incision one and a half inches in length was made one inch below and two inches to the right of umbilicus. Over a gallon of offensive, purulent material was thus removed from the cavity of the abdomen, and by means of an ordinary fountain syringe sterilized warm water was injected into the abdominal cavity, until it ran away again clear and without odor. A perforated rubber drainage tube was inserted in the wound. The patient experienced almost immediate relief from the operation. The abdominal cavity was washed out every twenty-four hours with sterilized warm water containing a little boric acid. After a few days this was done every forty-eight hours. His recovery was rapid and complete. His temperature in a few days fell to normal, and in three weeks he had entirely recovered.

He was carefully examined previous to the operation, and the only evidence he presented of tuberculosis was a limited dullness over the posterior surfaces of the apices of both lungs, with slight dullness on percussion and slight crackling on auscultation over the affected area. After he was convalescent, he was placed on cod liver oil and syrup of the iodid of iron, and I am informed that he is now (five months after the operation) in excellent health.

As has been well said by M. Watson Cheyne in his address delivered before the Section of Pathology, British Medical Association, at Montreal, September 1, 1897, tuberculosis, in the varying methods in which it attacks different portions of the body, presents some puzzling phenomena. As we all know, tuberculosis (the white death) in its various forms, causes about one-seventh of the entire number of deaths that occur annually from all diseases. Yet how varying is the progress and fatality of tuberculosis when it occurs superficially upon the skin as in lupus, when it occurs in the cervical glands, when it occurs in the lungs in the form we too well know as phthisis pulmonalis, or when it attacks the serous membranes of the abdomen and causes the disease known as tubercular peritonitis.

The life history of the bacillus tuberculosis as it is found in cases of lupus of the skin, would seem to indicate that it is not as virulent as many other pathogenic organisms. Cases of lupus are slow in progress, often exist for many years; and frequently only cause death when the patient's lungs become infected with the bacillus, thus causing phthisis pulmonalis. Why does this slow progress and fatality exist in lupus when contrasted with the acute and rapid infection of the system that we find in acute phthisis, or as it is often called, galloping consumption?

We believe that the true explanation of this is the nature of the tissues involved. When these bacilli

infect the skin, the irritation produced by them produces a layer of tissues around the bacilli through which they are often unable to pass, and the system is this way protected from their inroads. The same phenomena are often seen in postmortem examinations, on examining the lungs of persons who have died from other diseases than pulmonary consumption. In fact it has been conclusively shown that the vast majority of all persons, who die from any cause, after the age of 60 years, at some period or other of their lives have had deposits of tubercle in their lungs. These deposits of tubercle in the lungs often become surrounded or encapsulated by fibrous tissue, or may undergo calcareous degeneration and remain dormant during the lifetime of the individual. Unfortunately, however, this is not the usual history of tuberculosis of the lungs. The final destructive series of changes occurring in the lungs in phthisis pulmonalis, are due, not so much to the destruction caused by the bacillus tuberculosis, as to the infection of the system caused by the development and growth of myriads of pus-producing organisms, which attack the pulmonary tissues already weakened by the inroads of the tubercle bacilli.

The hectic fever with the debilitating sweats which

Lymphatic glands of peritoneum (rabbit).

accompany the later stages of phthisis pulmonalis, is evidently a septic infection by pus organisms. Tubercular infection of the peritoneum, however, in its rapidity of progress presents a marked contrast to most other forms of tuberculosis. As much damage may be done to the organism in a few days during the course of a case of tubercular infection of the peritoneum, as may be done in months or even years by other forms of tubercular disease. Why is this? The explanation of this is easily given by taking a look at the illustration accompanying this article, which is copied from J. Burdon Sanderson's *Hand-Book for the Physiological Laboratory*. The peritoneum, in fact in man and all higher animals, contains an immense mass of lymphatic glands and vessels, which probably comprise nearly one-half its area.

Absorption then from a structure of this composition goes on with immense rapidity, and putrid material of whatever kind, when it reaches the peritoneum, soon accomplishes its deadly work. Every physician knows how rapidly patients sink and die from the deadly peritonitis which follows perforation of the intestine in typhoid fever. Cases of abdominal surgery also where blood or serous exudation have escaped into the cavity of the peritoneum, and

have not been removed at the time of the operation, rapidly prove fatal from the same cause.

The treatment of purulent tubercular peritonitis by incision, either with or without drainage, is now thoroughly established by the record of such a large number of successful cases, that it is almost universally admitted by surgeons to be the proper procedure. An interesting query arises, how does the simple operation of incision cure? Many explanations of this have been given; some have believed that the entrance of air during the operation carried in at the same time other micro-organisms, which waged war upon and destroyed, by the formation of toxins, the tubercle bacilli. Other fanciful explanations have been given, which it is needless to repeat, but the true explanation is believed by the writer to be simply the bactericidal power of the lymph and blood serum which continually bedews the surfaces of the peritoneum.

As soon as the purulent material is evacuated from the abdominal cavity by drainage and thorough washing with sterilized water, the number of tubercular and other pathogenic bacilli present on the surface of the peritoneum, is reduced to a minimum. Nuttall has shown that the blood serum powerfully attacks and destroys all pathogenic bacteria and other harmful micro-organisms with which it comes in contact, and the living organisms become the victor in the fight, provided that the number of the invading micro-organisms is not too great. The battle between the hostile micro-organisms and the blood is just like that between two opposing armies. If the host of micro-organisms is not too numerous, the blood by the bactericidal power of its serum, vanquishes, and the result is the restoration to health, but if the powers of the system be weakened by any cause, or the number and virulence of the invaders are too great to be overcome, the pathogenic micro-organisms become victorious and the result is death.

SOCIETY PROCEEDINGS.

Michigan State Board of Health Quadri-Centennial and Conference of State and Provincial Boards of Health of North America.

Held at Detroit, Mich., Aug. 9, 10 and 11, 1898.

FIRST DAY.

The sessions of the first day were devoted entirely to the quadri-centennial of the Michigan State Board of Health.

The session was opened with prayer by Rev. JOHN MCCARROLL, the delegates joining in the recitation of the apostles' creed.

The president of the State's health board, FRANK WELLS, then made his annual address. Among other things he said:

"The last quarter of the century has been notable for the development of two sciences, biology and sanitation. The application of this knowledge to the saving of human life and the prevention of human suffering has kept misery and despair from entering countless homes. The honor and applause which everywhere greet the warrior who is moved by patriotism and duty to noble deeds is justly due to Dewey, to Shafter, to Sampson, to Schley and to Hobson. Shall we not place, side by side with these worthies, to be equally remembered with gratitude the names of Pasteur, of Lister, of Koch?"

Mayor MAYBURY welcomed the delegates and remarked that they had come to a city where the doctors do not live by curing diseases, but by making the healthy healthier. Residents of Detroit, affirmed the mayor, have on an average from ten to fifteen pounds more advoirdupois than the inhabitants of other cities.

Dr. GIBBS, Detroit's health officer, spoke for Gov. Pingree. In lauding the beauty of the city, Dr. Gibbs feelingly averred

that for him there was only one more removal to make, and that was from Detroit to heaven.

The first paper on the program, entitled "A Quarter-Century of Sanitary Work," was by A. N. BELL of Brooklyn, N. Y., but in his absence was read by Dr. Henry B. Baker.

This was followed by an address from Chicago's health commissioner, ARTHUR R. REYNOLDS, on

PUBLIC HEALTH WORK IN MICHIGAN.

His address showed how readily a naturally dry subject might be made exceeding attractive to the public. A summary of his remarks is as follows: What God hath wrought through this Board is told in the statement that between 1890 and 1896 nearly 150,000 cases of sickness were prevented and more than 7000 lives were saved from premature death through the advice, instructions and supervision of the Board. It is not too much to say that the State Board of Health of Michigan has, in the language of our great classic in hygiene, Edmund Parkes, made growth more perfect, decay less rapid, life more vigorous, death more remote for every citizen within the boundaries of this fair State. At first blush it may seem that the field of usefulness of a State board of health is a narrow one. On reflection, however, we will discover that its function is as broad as civilization itself. It follows the citizen in all his dealings, through all his days. It begins at his birth, it has him under observation, whatever his mission, through all his life to its close, and it keeps careful vigil at his grave until the last vestige of his remains is crumbled into the dust whence it came. Every incident that lowers the vitality, that depraves the mind or that whets an abnormal appetite calls for its interference. It holds no despot's sway to club mankind along paths that are hard. It only asks that he be normal. It teaches no abstruse philosophy, but offers hope and regeneration to the weak.

In this work of sanitation there is nothing of the spectacular. There is none of the inspiration and the glory that reckon with a nation saved or a foe repulsed by feats of arms. Nevertheless, those who study understand that the proper appreciation of sanitary science defeats man's most relentless foes, and that neglect or defiance of her laws has brought destruction to nations in all time. If unhappy Spain had no other sin than that of having maintained at our doors a preventable breeding-place for yellow fever, she richly deserves the wrath that has been visited upon her. The greatest number of deaths in the centers of population is caused by diseases of the nervous system, the worry diseases. The number is steadily increasing year by year, and this increase is due to the keenness of commercial competition and the fierceness of the struggle, not alone for existence, but for wealth. It is an almost universal rule that those who have labored and worried beyond their endurance leave a generation of weaklings to fritter away their substance and ultimately to pass from history forever. The lesson to be learned and the lesson that must be learned, is to stop fretting and stewing one's self into the grave, to leave a pitiful physical and mental inheritance to one's children. Natural law intends that man shall live and be useful, and not that he shall be degenerate or dependent, or that he shall prematurely die. The world is for man and his upbuilding, for the developing of his mental, moral and physical stature. The future sanitarian will broaden out upon this basis. He must educate the masses upon the known laws of reproduction and enable human beings to improve their breeding as the farmer improves all domestic animals by proper mating.

The remedy for the social evil that leaves such human wrecks in its wake must come through a thorough dissemination among the public of knowledge now chiefly held by those of the medical profession. Let parents and their daughters once fully understand the jeopardy girls are placed in by marriage with men who have lived reckless and impure lives, and there will be less need for surgeons to practice their art upon women in future. Let all understand that much of this danger and disease has its incentive in the semi-delirium caused by intoxicating drinks. When this is generally understood the young man who is known to be a rounder will not be hailed as a jolly good fellow, but as an evil thing to be shunned, as was the leper in the days of old.

But neither the sanitary millennium nor the social and economic millennium, nor the millennium of peace has yet arrived. Hellish war is still waged by civilized people and in the name of both God and the law, men are still legally marshalled out for slaughter. Sanitary science believes in war; but its warfare does not tend either to brutalize or to destroy life, but to save it, and to elevate it. Sanitarians believe in the war that regenerates and refines; the war for the defeat of Satan and the enthronement of Immanuel; a war whose weapons are reason, sweetness and light. To all who serve in such

warfare in this State, and to those who have brought sanitary work to its present perfection, I offer my most respectful homage. It is the Master's work, and I bid you Godspeed.

SANITARY WORK TWENTY-FIVE YEARS AGO

was then presented by Prof. R. C. KEDZIE, M.D. It was also put entertainingly.

At the afternoon session papers were read on the "Educational Work of the Michigan State Board of Health," by Prof. A. C. Lindeey, dean of Yale's medical faculty; on "Sanitary Conventions," by Benjamin Lee, M.D.; on "Annual Conferences of Local Health Officers," by C. O. Probst, M.D.; on "State Work for the Restriction and Prevention of Diseases," by John S. Fulton, M.D., and on "Municipal Restriction of Diseases," by Ernest Wende, M.D., Buffalo's Health Commissioner.

The evening session was occupied in five-minute addresses by various prominent sanitarians, among them Felix Formento of New Orleans, Hon. Le Roy Parker of Buffalo, Hon. John Avery of Greenville, Mich., Peter H. Bryce of Toronto, D. E. Salmon of Washington, J. N. McCormack of Bowling Green, Ky., C. L. Wilbur of Lansing, and J. N. Hurty of Indianapolis, and was followed by a reception and banquet.

SECOND DAY.

The morning session was occupied with the annual reports of the officers of the organization, presented by Benjamin Lee of Pennsylvania, president; Felix Formento of Louisiana, vice-president; Eleazar Pelletier of Quebec, treasurer, and J. N. Hurty of Indiana, secretary.

The report of the Secretary, Dr. J. N. Hurty of Indiana, showed an increase in membership for the year of three, one from Mexico and two from Canada. Secretary Hurty recommended that the conference adopt the old constitution of the national conference of boards of health, whose title was changed to the present one at the Nashville meeting last year. This was done with the exception of the annual dues clause, which is left to be prorated according to expenses.

The treasurer, Dr. ELEAZAR PELLETIER of Montreal, reported the reduction of debts left from the Nashville meeting of last year from \$357 to \$100.

The conference adopted a resolution asking compilers of vital statistics in the United States, Canada and Mexico to use the Bertillon system of making mortality census returns.

A by-law was adopted making it mandatory that on each alternate year the conference meet in Washington, on the ground that the attendance would be greater if a regular meeting-place were adopted.

After these business matters had been disposed of the convention settled down to the discussion of three questions suggested by the session yesterday, viz.: What are the principal lines of work of your board? How is such accomplished? What modification, if any, does the experience of your State suggest?

Dr. E. D. CROWLEY of Oakland, Cal., stated that the work of the State's health board is being vigorously pushed along three lines: The prevention of the spread of tuberculosis; the prevention of Texas fever in cattle, carried in from outside by the tick, and lastly, sanitary control over the State's harbors. In their efforts to stamp out tuberculosis in cattle, proposed legislative measures have been defeated again and again by a combine of wealthy cattle owners.

Professor LINDSLEY of Yale University spoke for Connecticut. The State Board there, he stated, had only advisory powers. The law governing sanitary measures in his legislature, he said, was to follow, never to lead, while the work of enlightening the public mind on sanitary reforms was like teaching a school where there were more truants than teachers. However, after twenty years' persistent work, the board is endeavoring to secure thorough sanitary administration in every town; to tabulate and publish vital statistics and have a thorough microscopic examination made of all water used for drinking and boiling purposes. One system of sanitary rules prevails in every town, and a county health officer is clothed with administrative power to see to their enforcement.

Delaware was represented by Dr. E. W. COOPER, who said his State Board was clothed with absolute power on its own inspection or on notice of grievance. It meets semi-annually and provides for a sanitary inspection throughout the State twice a year. Local boards are clothed with the same power as State boards, and education of the public along sanitary lines is carried on by means of circulars and public meetings held frequently.

Dr. J. A. EGAN, who represented Illinois, drew a picture of the State's sanitary condition. There is no mandatory statute enforcing the creation of local boards, and the business of the

State Board seems to be mainly the examination of doctors and midwives. No State Board of examining physicians is provided for. In one city of 15,000 population there is no health board, only a sanitary policeman, and disease runs rampant.

Dr. J. N. HURTY, for Indiana, said that the work of its State Board was hampered by defective legislative mechanism. Sanitary work is all crowded upon the secretary, who already has petitions from 250 towns asking him to come and investigate deplorable conditions.

At noon the delegates, with their ladies and guests, took cars for Parke, Davis & Co.'s laboratory, where luncheon was served. After a tour of inspection, the party were transferred to a steamer in waiting and given a ride to St. Clair Flats.

At the evening session the conference listened to a paper by GARDNER S. WILLIAMS, engineer of the Detroit water-works, on

PURIFICATION OF SURFACE WATER,

the opening wedge for a lengthy discussion. The paper was of necessity somewhat technical, dealing with experiments made with various purifying processes in relation to sewerage and bacteria, especially the typhoid bacillus. Mr. Williams stated at the outset that Detroit had never gone into the matter of purifying its water to any great extent, and he was therefore unable to give any extended local experiments. He referred to the development of purification of water in various countries, with copious explanations of the different processes. One of the points he made was that chemic analysis alone is not sufficient to show all the impurities of any certain water, but must be taken in connection with all available data concerning the source of supply, so as to establish a standard from which deductions can be made with any degree of certainty.

The question of filtration came up in connection with the main topic, and Dr. HURTY of Indianapolis, presented a number of stereopticon views of filtering plants, the most important of which was the sand filter in operation at Lawrence, Mass.

Mr. WILLIAMS did not commend the efficiency of mechanical filters, on the ground that they have not yet reached a stage of perfection rendering them thoroughly reliable, but they were championed by several physicians, who held that they not only gave satisfactory results, but were a necessity in small cities, where the first cost of the plant was the main question to be determined.

Dr. BRYCE of Toronto, said that one of the greatest factors for good water was the keeping of water in its state of natural purity.

THIRD DAY.

The Conference of State and Provincial Boards of Health closed its sessions with discussions on tuberculosis in all its phases. The walls of the convention were hung with maps showing that this insidious disease has killed more people than any other. Dr. Hurty of Indiana said one-seventh of all the deaths are caused by it. William Bailey of Kentucky declared that 1,200,000 people annually died from tuberculosis, and said that if sanitarians were but given the opportunity to fight the disease the saving would easily pay the country's pensions; that in two or three months the interruptions to commerce from the disease represented at least \$100,000,000.

After tracing the tubercle bacilli from its origin to the height of its growth in man, the conference discussed means of prevention. Discussions on this point ranged from "Care of Expectoration" to "State and Municipal Care of Consumptives."

The conference elected the following officers: President, of Toronto; secretary, J. N. Hurty of Indianapolis; treasurer, Felix Formento of New Orleans; vice-president, P. H. Bryce Eleazar Pelletier of Quebec.

PRACTICAL NOTES.

To Remove a Foreign Body from Under the Nail.—Alternately soften the nail with the end of a match dipped in caustic potash and scrape with a piece of glass until the object is reached. —*Journal de Méd. de Paris*, July 3.

Vesical Asthma.—One of the manifestations of autointoxication consequent upon hypertrophied prostate, is distress in breathing, which can only be relieved by emptying the bladder. *Semaine Méd.*, July 6.

Salt as an Antiseptic.—According to the *Cronica de Ciencias Médicas de Filipinas*, the insurgents dress wounds with dry

salt or strong brine, from lack of the usual antiseptics, and wounds from firearms heal under it in four to five days. — *Semana Médica*.

For the Disinfection of Sponges.—Sponges can be boiled without injury in 30 per cent. prophylic alcohol, Saul announces in the *Munich Med. Woch.* of June 14. He boils them two hours the first time; afterward thirty minutes. Anthrax spores are killed in ten.

Jequirity in Ozena.—Jequirity proved effective in a number of cases observed by Dr. C. Uriarte, that had resisted all other treatment. The after-effects vary with the individual and are transient, never serious. He uses it in a powder or salve, or in a 10 per cent. solution. — *Semana Méd.*, June 16.

Foreign Bodies in the Air-Passages.—Heller reports a number of serious cases in which prompt irrigation of the naso-pharyngeal space produced such efforts at expectorating or coughing, that the foreign body was expelled at once and life saved. He urges all to try this simple measure before resorting to tracheotomy. — *Munich Med. Woch.*, June 28.

Camphor Bromid in Chorea.—Bourneville and Katz describe a severe typical case of Sydenham's chorea rapidly cured with camphor bromid, increasing from 2 to 9 grams a day, March 9 to 22, again decreasing to 2 by April 6, confirming their previous announcements of its remarkable efficacy. The *Progrès Méd.*, July 16, contains cuts of the handwriting, during treatment and after it had become quite normal again, the final evidence of cure.

The Toxicity of Camphorated Beta Naphthol.—This has been established by Le Gendre and Desesquelle, who announce that the stomach will bear quite a large amount, if diluted in an inert liquid. The maximum for an adult is 1 c.c. a day. Injected into the peritoneum the daily maximum for an adult is 5 c.c. It can be incorporated with cocoa butter for a suppository; maximum 35 centigrams a day. The absorption is always slow, and as the camphor is most soluble, the toxic accidents that have been observed were probably due to the camphor. — *Presse Méd.*, June 22.

Abrashanow's Method of Amputatio Femoris Intercondylarica.—This method consists in sawing off the rear half of the patella, leaving the tendon still attached to the front, and after sawing off the lower end of the femur, cutting an oblong piece out of the posterior upper end of the tibia. The lower edge of this piece is then brought up to fit against the patella, while the long front edge fits the whole length across the stump of the femur. All the sawed surfaces are thus brought into juxtaposition, and the natural posterior surface of the upper end of the tibia, which has no bursa, forms the stump. — *Cbl. f. Chir.*, July 2.

Echinococcus of the Liver.—R. Lennhoff describes some observations (*Deutsche Med. Woch.*, June 30) which prove that an echinococcus can be differentiated by a peculiar furrow that accompanies each deep inspiration when the patient lies on his back. The abdomen rounds up smooth below the sternum except during inspiration, when the characteristic furrow between the sternum and the tumor attracts attention. A test puncture confirms the diagnosis. The patient should lie on his face a while before the removal of the cyst to dislodge the heavier contents from the rear.

Ox-gall in Biliary Lithiasis.—L. Gautier of Geneva has found that the prolonged administration of beef gall in small doses increases the solubility of the cholesterin and hence prevents the formation of gall-stones. He uses an extract reduced to one-tenth, decolorized, sterilized at 104 to 105 degrees C., combined with an inert powder, to make a pill containing 10 centigrams, one pill at the two principal meals. Patients formerly tormented with hepatic colic have no return of their attacks with this medication, which he continues or suspends according to indications. — *Semaine Méd.*, June 29.

Coagulating Injections for Erectile Tumors.—T. Anger has been using the following solution for this purpose for thirty years, with most satisfactory results: Water, 60 grams; sodium chlorid, 15 grams, and ferric chlorid, 25 grams, at 30 degrees C. He injects two to twenty drops in a small angioma and twenty to forty in larger ones, proceeding very gradually and limiting the injection to the part infected by peripheric compression of the tumor, left undisturbed for fifteen minutes afterward. The tumor subsides very slowly. If it has not all disappeared in three to six months he repeats the injection.—*Sem. Méd.*, July 6.

Success of Artificial Serum in Lead Colic.—The first indication is to purge and carry off the accumulated metal, but this is extremely difficult to accomplish, as purgatives usually refuse to act for several days. Prof. A. Delearde now announces that he has found that one injection of artificial serum will produce a copious diarrhea at once when there is lead intoxication, although in all other conditions it affects the kidneys, not the bowels. He considers it probable that the chlorid of sodium combines with the lead to form a soluble chlorid of lead, to which the prompt purging action is to be ascribed, which at once cures the pain, vomiting and headache. Paralysis is not affected.—*Nord Med.*, July 15.

Treatment of Strabismus.—At the July meeting of the Paris Academy of Medicine, Dr. Panas communicated some observations on this subject. He said that the squinting eye was the one which deviated most from the line of vision. Nevertheless strabismus was only apparently unilateral. If the phenomena accompanying this condition were analyzed in detail it would be found that the strabismus was always bilateral, and if it appeared unilateral that was because the patient only used the eye which was least affected, and in overcoming the deviation of this one exaggerated the obliquity of the other. As for therapeutic measures, Dr. Panas held that as the affection was bilateral there must be a bilateral operation. In 230 cases Dr. Panas performed tenotomy of both internal recti, and stretched them in addition, thus lessening their tendency to overaction. Dr. Panas never performs advancement, finding a simple tenotomy sufficient. In 220 cases he had never seen any overcorrection, or if there were a little it was only temporary. Of 220 convergent cases of strabismus, he had 190 in which the result was immediately successful. In those which were unsuccessful the result was not overcorrection but undercorrection. In ten cases Dr. Panas rectified this by advancement of the antagonistic muscles and in every case with success.—*London Lancet*.

The Laborde Treatment of Chloroform Asphyxia.—Herzog of Charkow has recently published in the *Deutsche Zeitschrift für Chirurgie* some experiments made according to Dr. Laborde's method (*vide JOURNAL*, Vol. xxx, p. 361, Feb. 12, 1898) of producing resuscitation in cases of chloroform and ether asphyxia by rhythmic traction of the tongue. The effect of making traction on the tongue is to stimulate its sensory nerves, and to bring about reflex contraction of the respiratory muscles through the medium of the central nervous system. Dr. Laborde recommends that the tongue should be seized firmly, and traction be made about twenty times in a minute. Up to the present time twelve cases have been recorded in which this method proved successful in asphyxia from anaesthetics. For the purpose of testing Dr. Laborde's conclusions, Herzog made a series of experiments on dogs partially asphyxiated by means of large doses of chloroform and ether and found that, in nineteen cases, respiration was restored spontaneously in six, but that traction of the tongue was only successful in resuscitating three of the remaining thirteen. In these three instances the animals began to breathe again after traction had been made twelve times, and their recovery was complete; in two other cases respiration was restored, but the

cardiac action nevertheless failed, and although the respiration was kept up for sixteen and six minutes respectively the pulse did not rally and the animals died. The results obtained by Herzog are thus at variance with those of Dr. Laborde, who obtained resuscitation in the great majority of cases. It is probable that Dr. Laborde commenced to make traction of the tongue at an early stage, when the animals were still capable of recovering spontaneously. The asphyxia obtained in Dr. Herzog's experiments always occurred in the last stage of the narcosis. Asphyxia in the early stage of the narcosis, while it is so frequent in the human subject, could not be obtained in the experiments on animals. Herzog concludes that Dr. Laborde's method is not reliable in the asphyxia of the last stage of narcosis, but that it may be tried as an auxiliary to other methods in the primary steps.—*London Lancet*, July 9.

Ureteral Surgery.—A recent editorial in the *London Lancet* treats of the above subject especially on the lines indicated in the last Huntarian Lectures on "The Surgery of the Kidney," delivered by Mr. Henry Morris. If the recent advances in the surgery of the kidney have surprised those accustomed to the old order of things, the modern surgery of the ureter excites still more astonishment. Numerous operations are now performed on the ureter, a structure which was quite recently considered to be wholly beyond the possibility of surgical interference. The first, and probably the most important, operation performed was ureterotomy for calculus, and though the operation is still rare, it has been done by several surgeons, and stones have been successfully removed from all parts of the ureter, from the pelvis of the kidney to the opening into the bladder. Strictures of the ureter have been relieved by ureterotomy, and in some cases a portion of the tube has been excised, with results which fully justify the operation. Ureteral anastomosis and ureteral grafting have received much attention in consequence of the frequency with which the ureter is involved in the operation of vaginal hysterectomy. Formerly the only hope which could be held out to a patient suffering from ureteral fistula after such an operation was nephrectomy, but ureteral anastomosis and grafting bid fair to entirely replace this severe procedure. A still more extensive operation on the ureter is excision. It is only called for in cases of widespread and persistent disease, but it has been successfully performed for tuberculosis and other conditions of the ureter. Another subject closely allied to the above is that of obstructive anuria. It is very rarely indeed that both ureters are simultaneously blocked by calculi. In most cases one kidney has been destroyed or rendered functionally useless by a stone, and then later, when the other kidney has taken on the double duty, it too, has had its ureter blocked by the impaction of a renal calculus. The symptoms which follow are identical with those met with after experimental ligation of both ureters in animals, and usually the symptoms which are commonly called "uremic" are absent. The patient survives a few days, perhaps as many as ten, and then dies. The fatal ending is inevitable unless the obstruction is removed. It has taken many years for it to be generally recognized that obstruction of the intestines can not be cured by the lavish administration of purgatives and that the obstructing cause must be removed or the bowel opened above the obstruction. In the precisely analogous case of obstructive anuria, diuretics and exercise are still only too often relied on for treatment, and a patient is allowed to succumb when an operation would have saved him. It is true that the percentage of spontaneous removal of the obstruction is greater in the case of the ureter than in the case of the intestine, but the principles involved are the same, and an operation should be performed as soon as the diagnosis is established. The lectures were illustrated by an elaborate set of tables of operations on the kidney, which must prove of great value in the preparation of statistics on this subject.

No. 61 Market Street (Occidental Bldgs.), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 20, 1898.

BLASTOMYCETIC DERMATITIS.

In July, 1896, Dr. GILCHRIST¹ described a case of skin disease, in which he found yeast fungi or blastomycetes. In March, 1898,² he published an extensive report of an additional case, and in the same month Dr. H. G. WELLS³ of Chicago, published a case from the surgical clinic and pathologic laboratory of Rush Medical College.

The *Indiana Medical Journal* for August, 1898, contains a report of a case by ROBERT HESSLER of Indianapolis. This concerns a thoroughly healthy man who, in October, 1897, received a slight cut while being shaved. This was situated in the neck, just under the chin, and on a line with the right angle of the mouth. Healing took place, but was followed by the development of an oval-shaped papule as large as a half-grain of wheat. This nodule was freely movable, hard, and remained stationary until January 10, this year, when it was noticed that it had become larger and was surrounded by an inflamed, slightly elevated area. Shortly after this it "came to a head." The surface was then cleansed, opened aseptically, culture-tubes inoculated and smear preparations made.

With EHRLICH's neutrophile stain there were found, in the interior of the leucocytes, characteristic yeast cells of a brownish color and slightly oval outline. Many of the organisms were in the budding stage. The agar tubes which were inoculated presented in a few days pure cultures in the form of small, bright, white colonies. The course of formation of daughter cells by means of budding could be followed readily in hanging drop preparations. When the organism

was cultivated on solid media for a longer time, Dr. HESSLER speaks of the appearance of characteristic fungus threads. As seen in stained preparations the single organisms are slightly oval, with a clear outer envelope and with differentiated contents.

Although the micro-organism is smaller than those described by GILCHRIST, Dr. HESSLER has concluded that it concerns a blastomycetes, and in this opinion he is confirmed by Professor WELCH of Baltimore, who has seen the cover-glass preparations.

The scar that formed after opening the abscess was much greater in extent than is ordinarily the case with similar abscesses due to the common pus microbes, and of late it has been noticed that a new papule about three-fourths of an inch from the site of the first one has appeared.

Now that the attention of the dermatologists and physicians in general has been called to the fact that blastomycetes may cause extensive lesions of the skin in various parts of the body, which, speaking generally, often resemble certain forms of tuberculosis of the skin, and which have therefore in some quarters been called instances of pseudo-tuberculosis, it is to be expected that many cases of this kind, which have heretofore been erroneously diagnosed, will be placed in their proper category.

NEUROLOGIC NOMENCLATURE.

It is a question for psychologists how far thought is possible without words, but it is a matter of common every-day experience that words are an essential in the conveyance of thought. They are tools, however, of varying convenience and value, according as they are properly chosen and fitted to the idea which they are intended to convey. The amount of extra labor that is involved in the expression of our thoughts by the lack of a suitable intelligible terminology is not readily calculated, but nearly every one has felt the mental strain of labored circumlocution when the proper terms were unknown or did not readily come to hand. It would be an interesting problem, if it were a possible one, to figure in terms of horse-power, let us say, the extra amount of energy required to express the daily range of ideas in a language like the German over that required in a less involved and complicated one, the English for example. With equal populations using the two it is easy to believe that the extra work could it be translated into motor power would be very real and appreciable by every ordinary intellect. When we consider the other methods of conveying ideas, we can still further magnify our estimate of wasted labor and add to it the oceans of ink that it is almost a justifiable exaggeration to say have been expended over and above the increased manual labor of writing, itself a tremendous strain in the aggregate.

It may be there is some compensation for this, that a clumsy language only affords a healthful gymnastics

³ New York Medical Journal, March 26, 1898.

for robust intellect, but it does not after all speak well for the intelligence that rests satisfied with imperfect methods or appliances when better ones are available. Sometimes it is an inert conservatism that perpetuates them, sometimes a sentimentalism that in its bes aspect is only halfway respectable keeps them in vogue. It seems also to many people a small matter to continue to endure abuses to which they have grown accustomed, and utterly needless to try to rectify them. When the evils are only a few extra and ill-adapted words or clumsy constructions of speech, the average man hardly thinks enough to feel their inconvenience.

How far science has suffered from the want of a convenient, economic and accurate terminology it is hard to say, but that it has suffered is not a matter for dispute. Our scientific terms, especially in medicine, have developed haphazard by accretion, and a really scientific system of nomenclature appears to have been about the last thing thought of. When the attempt has been made to make the terms descriptive the result has been mainly to make them cumbersome, and, in fact, it is impossible to have it otherwise. What is needed is a practical, brief, concise and easily adapted and utilized nomenclature, and this should be the aim.

The terminology of what may be called the finer gross anatomy of the central nervous system is the creation of the last thirty or thirty-five years at the most, but it has at present most of the defects of older systems, and it is safe to say is unintelligible to a large extent to the great mass of practicing physicians. Even the students that annually go out from our medical colleges have a very inadequate acquaintance with it as a whole, and probably soon forget a large part of that they have. Many of the terms in use are duplicated or triplicated, many more are needlessly cumbersome; as a whole there is no uniform plan or system. To read understandingly an elaborate anatomic paper on the nervous centers requires sometimes, nowadays, a knowledge of the terminology of the subject in two or three languages, so varied are usages of authors.

In the nomenclature of the Royal College of Physicians, which was adopted many years ago by the AMERICAN MEDICAL ASSOCIATION, and which is subject to decennial revision, the Latin, French and German equivalents are given.

For a number of years Dr. B. G. WILDER of Cornell University has been endeavoring to bring into use a simplified and consistent system of neurologic nomenclature, and the terms he has proposed have in many instances been adopted by prominent neurologists and seem likely to come into general use. A recent and exceedingly meritorious work, that of Dr. MILLS, adopts his system throughout, with the result that it affords almost the only consistently systematic nomenclature in any treatise of its kind on the disorders of the nervous system. For this reason, however,

it has been severely criticised, the average conservatism of the time reacting against what seems to it an innovation. Dr. WILDER's nomenclature has in it much that may seem novel, but its terms have the merit of brevity, are fully as descriptive or locative as those hitherto in general use, and the charge of cumbersomeness that has been thoughtlessly made against them in some of these criticisms has least of all a valid basis. Its adoption by Dr. MILLS is to be considered as an advance and an advantage rather than a disadvantage to his book, for even if the terms do not all of them come into general use, most of them probably will, and the work will be therefore all the more in the front rank of medical literature.

The need of a uniform and improved system of medical nomenclature generally is shown by the appointment of committees of anatomic societies here and abroad for its better regulation. That this is a favorable sign of the times will be admitted, and each movement of the kind has its influence in bringing about the desired result. The final perfected nomenclature will probably be to some extent an evolution, but all these preliminary attempts will have their influence in bringing it about, and probably none of them will be more influential in regard to nervous terminology than the elaborated and consistent system of Dr. WILDER, however much objectors may criticise and temporarily prevail. It is only an extreme conservative who will not desire something better and more consistent than the cumbersome, arbitrary and poly-nomial nomenclature now in use.

THE URINE OF THE MALARIAL FEVERS.

Even when no specific action of the causal factor of this disease is exerted upon the kidneys, the urine of malarial subjects varies somewhat with the type of infection, whether regularly intermittent or estivo-autumnal, as well as remaining to a certain degree subservient to physiologic influences, as amount of fluid ingested, season, climate, time of day, and the other usual considerations. In not a few cases, however, and it must be confessed that these are almost universally of the estivo-autumnal variety, the kidneys suffer severely, either in the production of an acute nephritis, or in the hemoglobinuria of pernicious ague, or both. Again, a former attack or attacks of ague may have gradually produced a chronic nephritis, upon which an attack of pernicious estivo-autumnal fever has engrafted an hemoglobinuria, as in the case reported by BROWN ("Malaria;" report of twenty-eight cases), in which granular and epithelial casts were found in addition to red corpuscles and "shadows;" the specific gravity in this case averaged 1010:

Let us first take up the urinary changes present in the average number of ordinarily severe cases. The daily amount varies as to whether a paroxysm has occurred on the day in question or not, for at the beginning of a paroxysm it frequently happens that a considerable amount of urine is passed. The quan-

tity also varies with the type of infection; in the regularly intermittents it is somewhat increased, while in the estivo-autumnal infections, when they cause a fever almost continuous in its action, the urine, as in all continued fevers, becomes diminished. When convalescence is established, usually several days after the last chill, a slight polyuria is often manifest; this rarely exceeds four pints and may last a few days or weeks, depending as a rule on the severity of the attack. As regards acidity, one would naturally expect that in fevers, concentration of the urine, other things being equal, would increase the acidity. This is true in the malarial fevers, except in cases of the estivo-autumnal type, where the urine is not altered in this regard. The color varies greatly: where fever is present it is high, and the higher the fever the deeper the color. This fact depends upon two causes: the concentration that occurs in all febrile processes; the chill with subsequent fever is coincident with the destruction of large numbers of red corpuscles, and at that time a large amount of pigment, transferred hemoglobin, is set free in the blood, to be immediately taken up by the leucocytes; while a part of this pigment is deposited in the various organs, especially the liver, no inconsiderable amount finds its way to the kidneys and appears in the urine as urobilin, which substance itself would lend deep coloring to the urine. Some cases of malaria show a jaundice more or less marked; this may vary from the slightest perceptible tingeing of the conjunctivæ to a deep yellow, the very dark colors so characteristic of obstruction never occurring in uncomplicated cases. This jaundice is always remotely hematogenous, a greater number of red corpuscles being destroyed than can be elaborated by the excreting organs; it occurs as a rule only in the severer cases, usually estivo-autumnal in character, cases in which not infrequently hemoglobinuria has supervened. In such instances bile coloring matter may be proved to be present in the urine by means of the ordinary nitric acid contact test.

As stated above, the jaundice is only remotely hematogenous; that is to say, it only primarily depends upon the destruction of the red corpuscles. The pigment is in large part carried to the liver and a great increase in the secretion of the bile occurs so as to rid the overcharged system of as much deleterious matter as possible. Indeed, the secretion is often so great that all cannot be disposed of through the excretory ducts; a backward pressure then occurs and reabsorption, with the production of jaundice, readily follows. In the icteric attacks, bile is not very apt to be in the urine, as the kidneys very probably are able to transfer into urobilin some of the biliary compounds. It is only when the latter are in great excess that the presence of bile can be proven. As in other febrile affections, with a diminished excretion of fluid from the kidneys, there is a normal or increased amount of solids, so that during

the paroxysms the specific gravity is increased, while in the intervals it is diminished, so that the total amount passed maintains a fairly good average, from 1045 to 1018. When infection is from the estivo-autumnal parasite, and the attack of sufficient severity to cause a continuous fever, the specific gravity, of course, remains permanently high. As concerns the various normal ingredients of the urine, urea and uric acid are increased as are the various salts, phosphates, chlorids and sulphates. The striking feature about this increase is that it is especially manifest during the post-malarial stage, the period of polyuria.

Another point of interest in the solid constituents of the urine is the increase in the amount of iron. This is augmented in any febrile disease, but more so in malaria than in any other. The increase is particularly liable to be noticed after a paroxysm, and is undoubtedly dependent upon the excessive destruction of red corpuscles. The sediment of malaria is unusual from but one standpoint and that is best brought out by the use of the centrifuge; the presence of black pigment occasionally of such quantity as to produce a heavy deposit in the bottom of the tube as in the case reported by Forchheimer. Among abnormal ingredients that might appear the first place must be allotted to albumen. In all febrile affections a varying proportion of kidneys suffer, some from temporary changes, as manifested by the presence of albumin and casts which gradually disappear after the cessation of the original disease; while others are the subjects of acute inflammatory processes which do not answer readily to treatment and which finally become chronic. In such a disease as the one under consideration, where specific organisms are present in the blood, naturally the delicate epithelial structure of the kidney would be almost certain to sustain some damage. Such indeed is the case here, and a large proportion of malarial infections show a slight amount of albumin with an occasional cast, usually hyalin. It is rather remarkable that under the provocation present an acute nephritis is of such uncommon occurrence. Probably of more consequence than the parasites in the production of inflammatory nephritic changes, is the irritation of the large amount of pigment set free in the blood and excreted, at least to some extent by the kidneys, as shown by its appearance as a sediment and chemically by the increase in iron salts. A well-known law of pathology tells us that slight irritation continued over a considerable length of time will inevitably result in the presence of new-formed connective tissue, which new-formed tissue will in the course of time most surely undergo cicatricial contraction. Many cases of malaria, especially in the more southern latitudes where the estivo-autumnal parasite plays the leading rôle, are the subjects of changes in the kidneys of a chronic inflammatory type, interstitial nephritis, as evidenced by increased secretion of urine, pale color,

low specific gravity, and the presence of a small amount of albumin with granular casts, even when the blood at the time of examination shows the patient to be free from active infection. This change is possibly due to the constant irritation of the pigment, and has been demonstrated in individuals, the victims of paludism, in whom a possible alcoholic etiologic factor can be positively excluded. The subject of malarial hemoglobinuria, while of great practical importance, is of not common occurrence, and is more properly treated under a separate heading.

THE TYPHOID FEVER OF THE ARMY CAMPS.

Sanitary men tell us that with our present knowledge of the causation of typhoid fever every death from that disease is an unnecessary death. This is an excellent principle to hold in view for the guidance of municipal health officers who have some control over the insanitary factors concerned in the spread of the disease and of military medical men serving with well disciplined troops, but we can hardly expect regimental surgeons serving with our volunteer troops at the present time to subscribe to it. Most of our hygienic authorities agree that hastily organized levies have to undergo a typhoid seasoning before they can be considered fit for active service, for every new regiment includes many young men who are susceptible to the disease and their number gives a corresponding susceptibility to the regiment, while the difficulties in the way of controlling the disease are very great. This was our own experience in the Civil War. In the first eighteen months of that war typhoid fever may be said to have been epidemic among the troops that were concentrated around Washington, D. C. In July, 1861, 2.20 cases occurred in every thousand of the 17,709 soldiers camped near the national capital; in August, 6.14 in every thousand of 50,608 men; in September a rate of 5.90 was recorded among 85,408 troops; in October, 7.23 among 113,204, and in November the highest rate of the year was reached, 10.89 cases in every thousand of 133,669 men, or a total of 1456 cases taken sick during that one month. In October and November of the following year, on account of new levies camping on old and infected grounds, the recorded rates rose to 14.49 and 17.84, while the actual rates were really much higher, as most of the cases reported as common continued fever were cases of typhoid infection not included in the statistics of typhoid.

In the JOURNAL of June 4, 1898, we pointed out the danger to our troops from this deadly camp fever as being greater than that from yellow fever, which at the time was exercising a depressing influence on the public mind. We held that unless special care were given to the sanitary condition of our camps, typhoid infection would be introduced and spread with disastrous results similar to those that followed the insani-

tary conditions of 1861-62. The first circular issued by Surgeon-General STERNBERG on April 25, four days after war was declared, urged on medical and commanding officers the importance of sanitary precautions for the prevention of disease in camps, and its publication was followed by arrangements for the supply of germ-proof filters to troops in the field. These measures, however, were insufficient to counteract the many opposing influences that were brought into operation by the sudden aggregation of large bodies of raw troops and inexperienced officers, medical as well as line. Typhoid fever infection, usually imported from state camping grounds, made its appearance in the large national camps and spread, but much less rapidly than during the concentrations of the civil war. At Camp Alger, Va., at the close of the second month of its recent occupancy, there had occurred in all only thirty-nine cases of fever among the 20,000 or more men on the ground, while at the corresponding period of 1861, the troops near Washington had already sent 8.34 out of every thousand men to hospital with typhoid fever. Toward the middle of July, however, reports from Alger, Chickamauga Park and other camps indicated a rapid increase in the prevalence of the disease, and special inspectors were sent to inquire into the conditions which occasioned the increase. These were found, in general, to be, not impurity of the water supply, but insanitary conditions due to want of knowledge on the part of the volunteer troops of how to take care of themselves in camp. At Camp Alger the water supply from driven wells was organically pure and protected from surface drainage by a thick stratum of impermeable clay; but the tents were crowded against each other and all were overcrowded with men. Regiments were cramped into an area insufficient for battalions, and, as a consequence, there was not room for a sufficiency of sink accommodation on the front or flanks of any of the commands. These sinks necessarily became infected and the disease in some regiments began to assume the proportions of an epidemic. Similar conditions prevailed in Chickamauga Park, Ga., where, in addition, sinks of suitable depth could not be dug owing to the underlying rock being so near the surface. At Tampa, Fla., the height of the subsoil water level necessitated the use of sinks so shallow that when heavy rains fell the infected contents were flushed out of them over the camp surface. These and other insanitary conditions due to continued occupancy led to prompt action by the War Department. Boards of officers were sent to inspect and select new sites for camping grounds and many of the troops are now under orders to march from the old to the new grounds. During a march of ten days or two weeks the cases of fever due to infection in the old camp will be developed and removed to hospital, so that the command on reaching its new site will be free from the disease, and its protection thereafter

will depend on the care given by officers to the sanitation of their camps. The chapter hereafter to be written in the medical history of the Spanish-American War on the development and suppression of the typhoid fever outbreak will be one of much interest to medical men and military sanitarians. It may do much to emphasize the fact that a death from typhoid fever is an unnecessary death. The War Department, meanwhile, has urged upon all officers, from the commanding general to the company commander, the exercise of the utmost vigilance to enforce proper sanitary conditions in camp, that the armies may profit by their recent experiences. We print the sanitary orders of the Department on another page of the JOURNAL.

THE RETURN OF SHAFTER'S ARMY.

Three months ago, that is when the invasion of Cuba was the subject of general interest, few medical men expected that our troops operating in that island would escape visitation from yellow fever. The profession was therefore not surprised when, about the middle of July, the announcement was made of the presence of the disease in the lines around Santiago. Fortunately the capture of the city and the removal of all armed resistance from its front enabled the army to devote the whole of its much exhausted energies to taking care of itself. Two methods of campaign, as it might be called, against this insidious foe were open to the military commanders. One was that of moving from camp to camp on the high grounds back of Santiago and removing the febrile cases and suspects until each regiment was free from the disease, when it could be embarked for Porto Rico or a United States port without danger to itself or to others. Medical men would probably have considered this the better course, but in view of the exhausted condition of the troops a call was made by the military authorities in Cuba for the adoption of the other, the immediate return of the troops to some locality in the United States where the danger of propagating infection would be reduced to a minimum. This involved the danger of a disastrous outbreak on some of the transports while en route, with quarantine detentions at the home port and the possibility of infection finding a landing and transmission to some part of the United States where the conditions were favorable for its development. Prior to this call, however, arrangements had been made by the President and the Secretary of War, after consultation with the Surgeon-General of the Army as to their feasibility, for the return of the troops that are not sick with yellow fever or with suspected yellow fever. Telegraphic instructions approved by the Surgeon-General were sent to Santiago to ensure the best sanitary conditions of the transports and of the troops and their baggage at the time of embarkation. These instructions read as follows:

1. Hold troops assigned to a transport under observation three to five days in separate camp not infected by fever.
2. Surgeons to inspect same twice daily, isolating promptly suspected cases.
3. Bathe and freshly clothe or sterilize old clothing of troops at the beginning of period of observation.
4. When not possible to detain troops in camps under observation, bathe them and freshly clothe or sterilize old clothing before embarkation, excluding, after searching inspection, suspected cases.
5. Yellow fever convalescents or suspects should not accompany healthy troops.
6. No equipage nor personal effects capable of conveying infection should accompany troops unless disinfected by steam or otherwise.
7. Arrange to embark by daylight under a careful supervision of surgeons, who will control sanitary conditions of troop-ships en route.

In the meantime a camp was laid out at Montank Point, L. I., for the accommodation of the troops, and provision was made for hospitals for the sick and wounded, for hospitals and isolation camps for yellow fever patients and suspects, and for the careful inspection of each transport and the troops brought by her prior to their disembarkation, with thorough disinfection of persons, clothing and other personal effects. Colonel WM. H. FORWOOD, Assistant Surgeon-General, U. S. A., is in charge of the medical department at the new camp. Passed Assistant-Surgeon G. M. MAGRUDER and Sanitary Inspector W. F. BRUNER, formerly inspector for this Government at the Port of Havana, are on quarantine duty as boarding and inspecting officers, and Drs. KINYOUN and HASTINGS have charge of the arrangements for disinfection. In view of these precautionary measures, we may expect to learn of the transfer of the army without mishap to itself or to the country.

CORRESPONDENCE.

The Medical Department of the Army.

CHICAGO, Aug. 9, 1898.

To the Editor:—Apropos of your editorial on the Medical Department of the U. S. Army and Navy, permit me to make a few suggestions.

My experience as Major and Surgeon of the First Ill. Cavalry, U. S. Vol., convinces me that the Medical Department of the Army, as at present constituted, is all wrong. My opinion of the Department as it exists at present is that it is both incompetent and inefficient, and I think this charge will be borne out by others of the volunteer surgeons in the service.

This condition of affairs is not to be wondered at when we take into consideration the various ranks of the medical officers. The Surgeon-General only ranks as Brigadier-General; the Deputy Surgeon-General as Lieutenant Colonel, and so on down the line. It goes without saying that men who are sufficiently endowed by nature with brains and ability to enable them to take an elevated position in this profession can not be induced to enter the army service when the highest position they can attain is that of Brigadier-General. We have seen

the melancholy spectacle of beardless boys among the combatants ranking men who had grown gray in the medical service. The experiences of the present war have proved that the Medical Department is of equal importance to the Field and Staff. We have seen that sickness and disease kill more men than do bullets; hence the demand for medical officers that will be fully equal to any requirements occasion may demand.

How can this be accomplished? It can be done by raising the rank of the Medical Department, so that the Surgeon-General of the Army will be a Major-General; a Deputy Surgeon-General a Brigadier-General, and so on all the way down. If this were done the Army Medical Department would be a desirable service, and would attract men of large ability.

Again, it is my opinion that the Medical Department should be made entirely separate. It should be cut loose from the line, the Quartermaster's and all other departments, and only in the matter of issuing rations should the Commissary be drawn upon. The Medical Department should provide its own transportation in the way of cars, hospital ships, and if necessary, transports. The commanding general should be required to notify the surgeon in charge when a movement was going to be made, what regiments were included, and when an engagement was to take place. Then the medical officers could make full provision for the care of the sick and wounded, and their transportation from the field of battle. Under these conditions there could be no shirking of responsibility, and the shameful sight of an altercation between the Commanding General and the Surgeon-General, such as we are now being treated to over the Santiago campaign, would be an impossibility.

If the Surgeon-General had been instructed to purchase all supplies required for the Medical Department, and if those instructions had been carried out in a competent and efficient manner, there could have been none of the horrors, such as our men had to endure during the present Santiago campaign, which were totally unnecessary and uncalled for. If the regimental and division hospitals at Santiago were no better equipped than those at Chickamauga, I feel sorry for them.

And now for the charges of incompetency and inefficiency. On my arrival at Chickamauga I reported to the Medical Director of the Department and asked for supplies for my hospital. I was asked what I had brought with me, and when I replied, "nothing," I was told that "that's the way with you volunteers, you come down with nothing and expect us to equip you." I said that I certainly expected to be equipped, as the State authorities told us to leave everything and we would be supplied by the U. S. authorities at Chickamauga. To make a long story short, it took me three or four days before I could get a drug supply, and that entirely inadequate.

Upon my arrival in Chickamauga I made requisition on the quartermaster for a hospital tent. It was nearly a week before I got that. Up to the time of my leaving Camp Thomas, every regimental hospital was most poorly supplied with even the necessities for daily use.

Under these circumstances what would we have done had we been suddenly ordered to the front? It would simply have been a repetition of Santiago.

The excuse for not equipping us properly was that we were to send all our sick to the division hospital. As my regiment was not attached to any division, I was told that I could not be supplied because they did not have the things I asked for supplied from Washington.

There were lots of cots at department headquarters, but it was days before I could get any. There were ambulances down there by the dozens, but up to the time of my departure I could not get a regimental ambulance, when I was entitled to two. Every day or so it was impressed on me that I must use the most extreme economy in the prescribing of drugs and medical supplies. As if I was going to wantonly waste the

property! Instead of being asked by the proper authorities what drugs and supplies I was in need of, and having this proper authority see to it that not only my regiment, but all other regiments were properly and thoroughly equipped with everything necessary to properly care for the sick and wounded, I was compelled to find out for myself to what my regiment was entitled, and then fight for everything I received. To cite an instance, I sent in a requisition and told them it was emergent. As I did not hear anything from it for two days, I went after the things personally, and was told by the Medical Director to go over to the first division hospital for the supplies. Among other things applied for was one gallon of castor oil and a pound of laudanum, with which to treat camp diarrhea, which was prevalent at that time. In response to my requisition the division hospital sent me twelve ounces of castor oil and one ounce of laudanum; the other articles were ignored.

These, Mr. Editor, are some instances of how the Medical Department was administered at Camp G. H. Thomas. If regimental hospitals were well supplied and equipped, then it would have been a very easy matter to have properly organized brigade or division hospitals when the troops were ordered to the front. All the regiments could have transferred their supplies to the general hospitals before an action came on, and have left them there as long as that division remained intact.

On the requisition list of the U. S. Army, which was handed me, there were no such articles as condensed milk, malted milk, nor canned soups of any kind. We were not supplied with sheets, pillows, pillow cases, nor any such articles of absolute necessity for a hospital. If I had not drawn upon my lady friends in Chicago, Springfield and elsewhere, for money to buy ice and milk, and for sheets, pillow slips and night shirts, I would have had a sorry looking hospital. If the Red Cross Society can supply all these things, why can not the Medical Department of the U. S. Army, with a rich, powerful Government behind it, equip its army hospitals beyond reproach? If numbers of medical men whom I could name had been placed at the head of affairs, our whole army would have been completely equipped with every medical and surgical necessity they could require, in *three days*.

I trust, Mr. Editor, that the horrible condition of things which existed at Santiago, as well as the disgraceful sanitary conditions of the various camps, will be investigated, and the whole Army Medical Department reorganized. To refer to requisitions: In one of my applications for supplies I asked for carbolic acid and boric acid. The carbolic acid was struck off my list, as the Medical Purveyor was instructed not to issue it. As I did not receive the boric acid I made inquiries as to why it was not issued, and was told there was none in the camp, as it was not supplied to the army. These are two of the most efficient and cheap antiseptics, which I had to do without. As I had a large number of infected arms, caused by men interfering with their vaccination dressings, it can easily be imagined what a fix I was in. As a result I had a number of axillary abscesses, and some of the men had fearfully swollen arms, which confined them to the hospitals or "quarters."

At Chickamauga there were thousands of men camped for months, during extremely hot weather, yet there were no ice-machines provided to furnish ice for the troops, nor were any provisions made to supply the men with ice, till Dr. Gill of the Red Cross Society made his appearance.

The foregoing are a few of the glaring instances of incompetency and inefficiency which occurred during my stay at the camp.

And now a few words as the water-supply. A number of the wells were drilled throughout the camp to supply water for drinking purposes. A pipe-line was run from the Chickamauga River to supply water for the horses and for washing purposes. The Chickamauga is a dirty, sluggish stream, which drains the greater part of that country. All the ditches

which drained the camp empty into that stream. The men were told not to drink that water, but when a lot of men are tired, hot and thirsty, injunctions of that kind are not heeded, and many of them drank frequently of the water. Not more than two miles farther on, a clear, pure, limpid stream issued from the rock at Crawfish Springs, in volume sufficient to have furnished the camp with water for all purposes. Why was this water-supply not secured instead of the Chickamauga River? The result is that typhoid fever is epidemic at Camp George H. Thomas, and the troops remaining there will, in all probability, have to be removed to other locations.

Trusting you will give this letter publication, in the hope that it may help to correct the glaring defects which exist in the army today, I am, sir, Very truly yours,

WM. CUTHBERTSON,

Late Major and Surgeon First Illinois Vol. Cavalry.

Condition of Santiago.

SANTIAGO, CUBA, July 15, 1898.

To the Editor:—I have just been through the city of Santiago de Cuba. The terms of capitulation will be published before this reaches you. I found the city full of stench and disease; no sanitation. Dead horses, dogs, cats and other animals that starvation had deprived of life are lying bloated and decomposing in the rough, dirty, narrow streets. Thermal fever, dysentery, acute diarrhea and yellow fever are disseminated through the city. The city water supply comes through an eight-inch main which is inadequate for a city of 60,000. The sewerage is almost *nil*. The refuse from the kitchen, such as starvation will give, is strewn into the streets to decompose in the hot sun and daily showers. The streets are full of deep holes, four or five feet wide by one to three feet deep, which speedily become receptacles for the decomposing animal matter and are so many cesspools of nauseating odor. General Shafter has wisely refused to let any of our troops pass into the city. More of Santiago in my next.

There are 26 cases and 3 deaths from yellow fever in the camp near Santiago, 146 cases at Sibone (pronounced Siboney). The number of deaths has not been received today. Of 140 cases of malarial, bilious and thermal fevers in four hospitals, 65 have been discharged for duty. Thirty-two wounded are still in the division hospital. The yellow fever hospital is three-fourths of a mile from the main camp on a hill. The fever hospital and division hospital for wounded are one-quarter of a mile apart.

Sanitation is improving and all doing well. Dr. Pope has worked heroically and deserves the thanks of the American people for his untiring efforts, although often unsuccessful.

Drs. Combs and Jones are in charge of the yellow fever hospital near Santiago; Dr. Wood in charge of the division hospital, and Dr. La Garde of the general hospital at Sibone.

Recapitulation: 1342 wounded in all of the battles since landing in Cuba; 100 deaths so far from wounds, killed and missing; 168 yellow fever cases and 28 deaths from the same cause.

ORLANDO DUCKER, M.D., U. S. V.

Malingering.

UNIONVILLE, N. Y., Aug. 10, 1898.

To the Editor:—I read the JOURNAL with great interest and profit every week. Your editorial on "Malingering" (p. 247, July 30) has just been read with keen interest and suggests that I give you an outline of a case in point.

Mrs. E. V. C., married, one child, aged 35 years, is of an extremely nervous temperament, light weight mentally, but with a glib tongue that elicits the sympathy of similarly constituted persons. Both parents are weak mentally, although father has brilliant spells, but lacks balance and judgment. In January and February, 1894, Mrs. C. had attacks of hys-

teria and believed she had a cancer of her uterus, which I told her she did not have, but she did not believe it. Every day or two she would have attacks of pelvic pains, a little diarrhea and a slight uterine discharge. During these months she had frequent hysteric convulsions with which she impressed her sympathizers that she had almost died, and it seemed to give her encouragement to have another if she could make her attendants believe she was nearly dead during her spell. She had some time before had an operation for lacerated cervix. Nothing would satisfy her but that nearly every day I must make some kind of an application to the uterus for treatment, and insert a tampon. This I did more to satisfy her than for any good it did. I urged cotton tampons soaked in glycerin and tannic acid and occasionally sprinkled a little powdered opium where it would come in contact with a slightly abraded cervix. I occasionally applied to the inside of cervix tincture of iodine, weak solution carbolic acid, etc. Two or three times I made an application of a weak solution of nitrate of silver (3 gr. to 3i) in the usual way with the applicator wound with cotton. Using silver nitrate was done more for its mental effect than for any good I hoped to accomplish, for I knew she would try to find out all about nitrate of silver, and finding it to be a strong drug it would satisfy her intense desire that I should use powerful remedies to "kill her cancer." I reckoned wrongly for she soon fell into the hands of a clairvoyant and he told her that she had no cancer, which she promptly believed, but told her that her doctor had "burned her insides all out with nitrate of silver." He easily convinced her that she had no cancer, which I was unable to do, and as easily convinced her that I had ruined her health under the use of nitrate of silver. She soon wanted me to pay her damages for "ruining her health and burning her insides all out."

Physically she is a strong, robust and healthy woman, and is on the go all the time and has been since I quit attending her, Feb. 27, 1894. But most of the time she has been malingering and now and then would work herself up to that pitch where she would either write me a letter or get a lawyer to, demanding damages. These I never paid any attention to except to send them back to her. She has now within the last few days gotten a reputable firm of lawyers to sue me for malpractice. I am interested to know what kind of a case they can work up. It is my candid opinion that she has, with the sympathy of her few mental equals, worked herself up to a belief that I will pay her several hundred dollars rather than have the matter come in the courts.

Are not physicians constantly in danger of expense and trouble from these people, if they treat them, and of annoyance and criticisms if they do not? Truly,

F. W. DENNIS, M.D.

Objects to New Designation.

SHELBYVILLE, IND., Aug. 15, 1898.

To the Editor:—I object to the proposed new designation for our profession, suggested by Dr. Fenn in the JOURNAL of August 13. Dr. Sternberg, in his address at Denver, did not recommend the adoption of the title "New School of Scientific Medicine," but merely said, "If we are to be characterized by any distinctive name, this would be the only one applicable."

From the days of Hippocrates to the present, we have always been the scientific school of medicine according to the best light we had. The celebrated John Hunter one day said to a member of his class whom he noticed taking notes during one of his masterly lectures on inflammation, "Don't take any notes of what I say today on this subject; I may not think next year as I think today." He was always a member of the "new school of scientific medicine," and kept abreast of the times.

We should always object to the titles "old school" or "allopath," names given to us by the eclectics and homeo-

pathe, and simply call ourselves physicians, without any annex or prefix. It almost seemed a necessity for us to semi-officially adopt the word "regular," which, in my opinion, is the only designation we should ever use, and only using this for the information and benefit of the laity. The word "regular" has been the subject of more criticism than any ten sentences in our "Code of Ethics." In the old "Army Regulations," in paragraph 1544, when describing the essential qualifications of one who aspires to an appointment in the medical department of the army, among other requirements is found this very emphatic one, "And he *must* be a graduate of a *regular* medical college."

During the war of the rebellion, a committee was appointed from the eclectic and homeopathic medical schools of New York and Philadelphia to correspond with Surgeon-General Hammond and inquire of him as to the meaning of the word "regular" as used by the Government. His reply was dated from the War Department, Surgeon-General's Office, Washington, D. C., June 1, 1863, and was as follows: "The term 'regular' is used in its most comprehensive sense, as indicating that a college is well-equipped and prepared to cover the whole ground of the science and art of medicine and surgery in its teaching."

Then, if we are to be designated by any distinctive name, I think that the only one that is applicable is the word "regular," which has been officially defined by the medical department of the United States, and more than fifty years ago was adopted by our "Code of Ethics," and which always represents progressive scientific medicine throughout the civilized world.

Respectfully,

W. GASTON MCFADDEN, M.D.

Wounds Requiring Operation.

RESERVE AMBULANCE COMPANY, TAMPA, FLA., Aug. 10, 1898.

To the Editor:—In your issue of July 30, I notice that an official report, rendered by me on returning with wounded from the fracas near Santiago, serves as a basis for editorial comment. Permit me to correct the statement there credited to me that "surgical operations were required only in shell wounds," a rather more sweeping assertion than I should care to be responsible for. It is, however, true that shell wounds were invariably serious and almost always accompanied by such extensive laceration and comminution as to render grave operative interference necessary. Mauser wounds, on the contrary, were usually humane and, with the undeformed bullet, were quite free from the so called explosive effect anticipated by the theorists, but they nevertheless occasionally required surgical operations of a more or less serious character. "Key-hole" wounds and those produced by deformed bullets sometimes presented such extensive destruction as to necessitate operation, but the proportion of such operations was surprisingly small. Mauser wounds were "trivial" as compared with those produced by large caliber bullets, on account of the greatly lessened destruction of tissue and the almost total absence of wound infection.

Very respectfully,

EDWARD L. MUNSON, Capt. and Asst. Surg. U. S. A.

Precocious Pregnancy; Twin Births.

MONTEVALLO, ALA., Aug. 6, 1898.

To the Editor:—I wish to mention the case of a negro girl whom I delivered of twins, Feb. 5, 1897. This girl was born and raised in Bolling, Ala. At 11 years of age, she began to menstruate regularly; became a prostitute soon afterward, and was delivered of twins at the age of 13 years, 9 months and 5 days. Both children were females. One is living; the other was accidentally smothered when five days old. The first child presented feet foremost; the second came "head

first." The afterbirth was adherent. I administered chloroform and, after introducing the hand, detached it. There was some hemorrhage, but a hot douche controlled it. The mother was exceedingly well developed for her age and made a speedy recovery. I inclose a copy of the birth certificate.

Very truly yours,

D. L. WILKINSON, A.B., M.D.

Antitoxin.

PHILADELPHIA, PA., Aug. 8, 1898.

To the Editor:—We beg to inform you that the validity of Letters Patent on Antitoxin recently granted by the U. S. Patent will be duly tested in the proper courts. We write to authorize you to make the public statement that we will protect to the utmost, purchasers and users of Mulford's concentrated antitoxic serum and other antitoxins. We hasten to make this in order that the demand for the remedy, which increases as the season advances, may be supplied without delay or hesitancy.

We have secured the services of W. Horace Hepburn, Esq., and Howson & Howson, competent attorneys of this city, to represent us, and have no doubt but that the claim will be disallowed, in justice to our country in general, and each family in particular.

Thanking you for your interest in the matter, we remain

Yours very truly,

H. K. MULFORD COMPANY,

By H. K. Mulford, Vice-president.

ASSOCIATION NEWS.

Rush Monument Fund.—*To the Editor:*—The following subscriptions to the Rush Monument Fund have been received:

June 21, Maine Medical Association (through Dr. Chas. D. Smith, Secretary)	\$ 100.00
June 20, Committee of Arrangements, Philadelphia Meeting American Medical Association (through Dr. Thos. G. Ashton, Treasurer)	185.68
July 20, Subscriptions at Denver Meeting American Medical Association (through Medical Director Albert L. Gihon, Chairman):	
From Colorado	2,000.00
From New York	2,000.00
From Ohio	336.25
From Indiana	320.90
From Tennessee	130.00
From California	110.50
From Wisconsin	78.00
From Texas	36.50
From Med. Director Albert S. Gihon, U. S. N.	25.00
Total	\$5,322.83
Reported to American Med. Association at Denver	4,424.27
Total expenditures	\$9,747.27
Total funds in hand	112.25
	\$9,635.02

The above sum, in cash and secured investments, has this day been transferred to Dr. Henry D. Holton of Brattleboro, Vt., who was elected Treasurer of the Committee by vote of the Association at the Denver meeting. Dr. Holton will be glad to receive and acknowledge further subscriptions to the fund.

GEORGE H. ROHE,

Secretary Rush Monument Committee.

BALTIMORE, Aug. 9, 1898.

Rush vs. Hahnemann Monument Fund.—Every visitor to the AMERICAN MEDICAL ASSOCIATION remembers the difficulties encountered by the Rush Monument Fund Committee in its work. The statement has been made at these meetings that the Homeopathic fraternity, with a much smaller membership, had raised a much larger fund, and were having executed a much finer monument to Hahnemann than the one contemplated to Benjamin Rush. Now cometh the statement that the Hahnemann monument is finished, but that it is not in place and will not be until the profession comes forward with the sum necessary to pay for it. What the delinquency amounts to is not stated further than that "three dollars from each

homeopathic physician in America would liquidate all claims and place the monument in Washington."—*Columbus* (Ohio) *Med. Jour.*, August 2.

SOCIETY NEWS.

New York State Medical Association.—The regular annual meeting of the New York State Medical Association will be held at 64 Madison Avenue, New York City, on Oct. 18, 19 and 20, 1898. The following is the preliminary program:

A Practical Demonstration in the Reduction of Infantile Mortality, by Dr. E. F. Brush of Mount Vernon.

The Pneumogastric Nerve in the Production of Stomach Disease, by Dr. Julius Pohlman of Buffalo.

The Coccyx, by Dr. J. E. Walker of Hornellsville.

Drugs versus Cardiac Insufficiency, by Dr. C. T. Osborne of New Haven.

The Passing of Alcohol, by Dr. J. M. Farrington of Binghamton.

A New Method of Amputation at the Knee-Joint Applicable in Cases of Senile Gangrene of the Foot, by Dr. Stephen Smith of New York.

Anthropologic Rambles in the Orient, Especially in the Island of Java, profusely illustrated with stereopticon views, by Dr. H. Ernst Schmidt of White Plains.

Dental Pathology in its Relationship to General Health, by Dr. Dwight L. Hubbard of New York.

Subnormal Temperature, by Dr. Leroy J. Brooks of Norwich.

Ancient and Modern Animal Products Used as Medicines, by Dr. T. J. Acker of Croton-on-Hudson.

The Treatment of Cases of Pulmonary Tuberculosis that Cannot go Away from Home, by Dr. Delancey Rochester of Buffalo.

Some Observations of General Interest Regarding the Course and Management of Cataract, by Dr. J. H. Woodward of New York.

Technic and Use of Saline Infusion, by Dr. Thomas F. Reilly of New York.

What to Do to be Saved, being the Conclusion of the Inquiry into the Abuse of Medical Charity, by Dr. Thomas J. Hillis of New York.

True and False Medical and Other Charities, by Dr. Wickes Washburn of New York.

A paper by Dr. Charles Phelps of New York, title not yet announced.

Genital Neuralgia and the Genito-reflex Pains, by Dr. F. P. Hammond of New York.

Lantern Slide Exhibition, by Dr. S. Alexander of New York.

A Case of Attempted Obliteration of the Deformity in Pott's Disease, by Dr. Charles Alling Tuttle of New Haven.

Notes on Neuralgic Affections of the Head, by Dr. Gustavus Eliot of New Haven.

The Use of Catgut Sutures in Ventrofixation of the Uterus, by Dr. J. E. Janvrin of New York.

Traumatic Tetanus; Report of a Case Following an Attempted Operation, Treatment, etc., by Dr. Z. G. Lusk of Warsaw.

Some Thoughts on Rational Treatment of Disease, by Dr. Chauncey P. Briggs of Ithaca.

Senility, by Dr. F. W. Higgins of Cortland.

A Case of Extrauterine Pregnancy Operated Upon at Term, by Dr. Eli Van de Warker of Syracuse.

Memoranda, by Dr. H. D. Didama of Syracuse.

Diagnosis and Surgical Treatment of Renal Calculus, by Dr. N. Jacobson of Syracuse.

Eye Lesions in Some Diseases of the Kidney, by Dr. H. S. Oppenheimer of New York.

Insanity Following Surgical Operations, by Dr. W. D. Granger of Bronxville.

Dermoid Cysts of the Ovary, by Dr. C. E. Fritts of Hudson.

The Operative Cure of Inguinal Hernia in Men, by Dr. E. D. Ferguson of Troy.

Urethral Stricture, by Dr. J. W. S. Gouley of New York.

A Discussion on Intestinal Obstruction, comprising the following papers:

Introduction, by Dr. Parker Syms of New York.

The Causes of Acute Intestinal Obstruction, with a Description of Their Mechanism, by Dr. E. D. Ferguson.

The Causes of Chronic Intestinal Obstruction, with a Description of Their Mechanism, by Dr. J. D. Bryant of New York.

Intestinal Obstruction Due to Impaction of Feces, Gall Stones, Foreign Bodies, etc., by Dr. J. W. S. Gouley.

The Diagnosis and Indications for Treatment of Acute Intestinal Obstruction, by Dr. J. D. Rushmore of Brooklyn.

The Diagnosis and Indications for Treatment of Chronic Intestinal Obstruction, by Dr. Leroy J. Brooks.

Intestinal Obstruction Due to Intussusception and Volvulus, by Dr. John F. Erdmann of New York.

The Technique of Operative Treatment of Intestinal Obstruction, by Dr. Frederick Holme Wiggin of New York.

PUBLIC HEALTH.

Transmission of Typhoid Fever Through the Air.—Germano has published the results of experiments made at the suggestion and under the direction of M. Kruse, and having for their object to study the possibility of the transmission of typhoid fever through the air. These experiments, made with different specimens of earth and substances infected by Eberth's bacillus, demonstrate that these organisms do not long resist complete dessication. For this reason the author claims that the spread of typhoid fever by means of dry dust is impossible, and that the assertion of certain authors, Troidboise among others, that the infection may spread several meters through the air is scarcely probable. On the other hand, the experiments of Germano, as well as of other writers, appear to prove that, in certain conditions of humidity, the pathogenic agent of typhoid fever not only remains alive for a rather long period, but may even preserve its vitality when in a condition of apparent dessication. Conditions favorable to transmission are produced, above all, when typhoid bacilli adhere to subjects which easily retain moisture, such as linen, cloth, earth, dust and fecal matter. Even in these circumstances, however, the microbes generally perish after dessication although some of the most resistant survive. The danger consists not so much in particles of these substances being carried through the air, since, when the mechanical fragmentation is carried to an extreme degree, the microbes perish, as in the fact that such particles may gain access to the mouth of susceptible subjects. The essential danger of propagation of the typhoid bacillus lies in the power of the organism to live for a long time when dessication is incomplete. This property may explain the spread of many epidemics.—*Health.*

Aerial Convection of Smallpox.—That a smallpox hospital in a poor and crowded locality may be, and usually is, a source of infection to the surrounding neighborhood is not denied; it is when we come to inquire for the causes of the spread in its vicinity that doubt and difficulty arise, and it is impossible to agree with Dr. Priestly that so long as a smallpox hospital is allowed to be a source of danger, whether it be by aerial infection or by maladministration, it does not concern a medical officer of health as a matter of fact, for the question is not merely of academic interest, seeing that its solution must be of some importance, not as an argument for or against placing smallpox hospitals in crowded localities, but in view of the selection of a site within a mile of any human dwelling. In every smallpox epidemic it is found that a certain percentage of cases around a hospital can be traced, apart from any question of maladministration, to ordinary known channels of infection, such as the incomings and outgoings of nurses, staff, tradesmen, patients, and friends of patients, and these are and must invariably be intensified as we approach such a center as a smallpox hospital; but even after the most searching inquiry a residuum remains to which no clue has been discovered, and of these it is said that they diminish in number as we get farther from the hospital, which is not invariably the case, and that they are not in excess along the main approaches, which we should have no right to expect, for the people who walk in a street are not always those who dwell in it. The elimination of this residuum is always a matter of extreme difficulty, as has been shown even when the investigation has taken place dur-

ing the progress of an epidemic, much more after a lapse of weeks or months, yet it is upon the complete elimination of these cases that the theory of distal aerial infection is based. That the theory has never been disproved is no argument in its favor, for the same might be said of the wonders worked by the diviner's rod. The main question is whether the theory fits in with the facts; if it does not, then it has not come to stay, but must make way for some other that will. Observations are wanted, especially in the country, where facts can be ascertained with much more precision than in a populous center. There must be many available from medical officers of health and medical practitioners throughout the country if only they could be collected. The chief difficulty, however, in accepting the distal infection theory remains to be noticed, viz., the startling immunity which has over and over again been observed in large bodies of presumably susceptible individuals living near to smallpox hospitals and among whom, according to the distal aerial theory, smallpox should have appeared with an intensity proportioned to their nearness to the center of infection. No explanation is offered for these remarkable exemptions from the incidence of a disease which (within limits still undefined) is acknowledged to be infectious above all others, and when it is borne in mind that by the chance discovery of its origin in a single case a clue might be given which would sweep away the better part or even the whole of the residuum on which the "circle argument" is based, the conclusion is irresistible that the theory of distal aerial infection rests on a very imperfect basis and that much more evidence is required before it can meet with general acceptance.—*London Lancet*.

Vital Statistics for June, 1898, in the State of New York.—June is always, next to November, the month of least mortality in this State; with an average daily mortality of 320 for the entire year, for the past ten years, that of June has been 294. The daily average for the past month reported has been 288, that of the five months preceding having been 325. Compared with the preceding month of May there were 1100 fewer deaths reported, of which decrease 300 occurred in the maritime district; the death-rate has lessened from 17.15 per 1000 population to 16.00. Aside from diarrheal diseases there were 100 fewer deaths from zymotic diseases this month. Diarrheal diseases caused 250 more deaths than in May. From acute respiratory diseases there were hardly more than half as many deaths, there having been about 700 fewer than in May, and there were 120 fewer deaths from consumption. Diseases of the digestive organs caused more deaths than in May, but other local diseases show a considerable decrease. Accidental deaths, many of which were from drowning, caused an increase of 100 over May. Fewer deaths from old age occurred this month. Compared with June, 1897, there were fewer deaths in all of the sanitary districts, the maritime district reporting 150 fewer, and in the entire State the reported mortality is less by 400, and by nearly as many is it less than the average of June for the past ten years. A large part of this decrease is in the mortality of early life, and one-half of it is in zymotic diseases. There is also a considerable decrease in acute respiratory diseases. Diarrheal diseases caused 375 deaths, half the usual mortality for June. Diphtheria caused 175 deaths, or 50 less than in May, and one-half that of June, 1897. Whooping-cough caused 111 deaths, the same number as in May and double that of last June. Cerebrospinal meningitis is also very much more prevalent than a year ago, 110 deaths being reported from it, which is excessive, all the sanitary districts reporting it, but the increase is mainly in the maritime district. Consumption shows the usual June mortality, about 1000 deaths. Smallpox has developed in no new localities since the report of last month. All of the ten reported localities, except Fredonia and Moravia, are believed to be free from the disease

and these are probably soon to be relieved. Of the 50 cases in all, 8 occurred in the troupe importing it; the cases have been generally very mild, no fatality occurring. The mean temperature for the month was 1 degree above the normal of 66 degrees, the average highest being 90 degrees, lowest 43 degrees; there were ten clear days and a slight deficiency for the State in rain-fall, although this was excessive in the eastern part of the State; winds southwesterly.—*Bulletin of the State Board of Health*, New York.

Health in Chicago.—The report of the Department of Health for July gives the total deaths for the month as 1938, a rate of 1.20 per 1000 as compared with 1.44 for July, 1897, and 1.52 for July, 1896. Of these deaths, 614 were of persons under one year of age, and 241 between one and five years. The principal causes were: Diseases of the nervous system, 246; diarrheal diseases, 247; other acute intestinal diseases, 208; consumption, 163; heart diseases, 119; pneumonia, 77; typhoid fever, 55; diphtheria and membranous croup, 48; cancer, 48; bronchitis, 34.

Circular No. 5.—

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE,
WASHINGTON, Aug. 8, 1898.

The attention of medical officers is invited to Circular No. 1 from this office dated Washington, April 25, 1898.

The extensive prevalence of typhoid fever in camps of instruction indicates that the sanitary recommendations made in this circular have not been carried out. If medical officers have failed to make the proper recommendations as indicated, the responsibility rests with them. If the recommendations have been made and not acted upon by those having authority in the various camps, the responsibility is not with the Medical Department, but these recommendations should be repeated and commanding officers urged to move their camps at frequent intervals and to maintain a strict sanitary police.

GEO. M. STERNBERG, Surgeon-General, U. S. Army.

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE,
WASHINGTON, April 25, 1898.

Circular No. 1.

In time of war a great responsibility rests upon medical officers of the Army, for the result of a campaign may depend upon the sanitary measures adopted or neglected by commanding generals of armies in the field. The medical officer is responsible for proper recommendations relating to the protection of the health of troops in camp or in garrison, and it is believed that, as a rule, medical officers of the United States Army are well informed as to the necessary measures of prophylaxis and the serious results which infallibly follow a neglect of these measures, especially when unacclimated troops are called upon for service in a tropical or semitropical country during the sickly season. In Cuba our armies will have to contend not only with malarial fevers and the usual camp diseases—typhoid fever, diarrhea, and dysentery—but they will be more or less exposed in localities where yellow fever is endemic, and under conditions extremely favorable for the development of an epidemic among unacclimated troops. In view of this danger, the attention of medical officers, and of all others responsible for the health of our troops in the field, is invited to the following recommendations:

When practicable, camps should be established on high and well-drained ground not previously occupied.

Sinks should be dug before a camp is occupied, or as soon after as practicable. The surface of fecal matter should be covered with fresh earth or quicklime or ashes three times a day.

New sinks should be dug and old ones filled when contents of old ones are two feet from surface of ground.

Every man should be punished who fails to make use of the sinks.

All kitchen refuse should be promptly buried and perfect sanitary police maintained.

Troops should drink only boiled or filtered water and coffee or tea (hot or cold), except where spring water can be obtained which is pronounced to be wholesome by a medical officer.

Every case of fever should receive prompt attention. If albumin is found in the urine of a patient with fever it should be considered suspicious (of yellow fever) and he should be placed in an isolated tent. The discharges of patients with fever should always be disinfected at once with a solution of carbolic acid (5 per cent.) or of chloride of lime (6 oz. to a gal-

lon of water), or with milk of lime, made from fresh quicklime.

Whenever a case of yellow fever occurs in camp the troops should be promptly moved to a fresh camping ground, located a mile or more from infected camp.

No doubt typhoid fever, camp diarrhea, and probably yellow fever are frequently communicated to soldiers in camp through the agency of flies, which swarm about fecal matter and filth of all kinds deposited upon the ground or in shallow pits, and directly convey infectious material, attached to their feet or contained in their excreta, to the food which is exposed while being prepared at the company kitchens, or while being served in the mess tent. It is for this reason that a strict sanitary police is so important. Also because the water supply may be contaminated in the same way, or by surface drainage.

If it can be avoided, marches should not be made in the hottest part of the day—from 10 A.M. to 5 P.M.

When called upon for duty at night or early in the morning, a cup of hot coffee should be taken.

It is unsafe to eat heartily or drink freely when greatly fatigued or overheated.

Ripe fruit may be eaten in moderation, but green or over-ripe fruit will give rise to bowel complaints. Food should be thoroughly cooked and free from fermentation or putrefactive changes.

In decidedly malarious localities, from 3 to 5 grains of quinin may be taken in the early morning, as a prophylactic, but the taking of quinin as a routine practice should only be recommended under exceptional circumstances.

Light woolen underclothing should be worn, and when a soldier's clothing or bedding becomes damp from exposure to rain or heavy dews the first opportunity should be taken to dry it in the sun or by fires.

GEO. M. STERNBERG,
Surgeon-General U. S. Army.

[NOTE.—Circular No. 3 is the last of the series of 1897.]

NECROLOGY.

JOHN B. HATTON, M.D., Des Moines, Iowa, died August 7. Dr. Hatton was born in an Indian camp in Monroe county, Mo., July 7, 1839, the last of thirteen children. When 17 years of age he entered a subscription school, paying his tuition with money earned from working on a farm. Later he began the study of medicine under the instruction of his brother. Afterward, in the winter of 1859-60 he secured the advantages of a lecture course in the College of Physicians and Surgeons at Keokuk, Iowa. While thus preparing himself the Civil War occurred and he enlisted in Company F, Thirty-fourth Iowa volunteers, and was elected first lieutenant of the company. Oct. 15, 1862, he was mustered into the service and commissioned as first lieutenant. The regiment took a prominent part in the "three days' fight at Chickasaw Bluffs, Miss., under Sherman, later in the great battles about Vicksburg, and was present at the surrender of Pemberton and his army, July 4, 1863. Afterward the regiment participated in the battles which ended in the capture of Forts Gaines and Fisher. Dr. Hatton was made assistant-surgeon, and when the captain of his company, being wounded and unable to retain command, resigned, he was appointed to the place in November, 1864. He located in Des Moines in 1890.

RICHARD M. SWEARINGEN, M.D., New Orleans School of Medicine 1867, and Louisville Medical College 1886, died at his home in Austin, Texas, August 7, in his 60th year. He was State Health Officer of Texas for twelve years. For his efficient service during the yellow fever outbreak on the Gulf coast in 1897, he will be long remembered, notwithstanding his unmerited unpopularity with the business community.

JOHN H. PICKETT, M.D., Buffalo, N. Y., 1865, died August 9, in Elizabeth, N. J., of which city in 1884 he was a defeated candidate for the mayoralty. He was a war veteran, prominent in temperance circles and until his health failed was a surgeon of the N. J. Central Railroad. His wife died several years ago, and so far as known he has no living relatives.

CARL E. ELSNER, M.D., Halle, 1874, died at his home in New York City, August 8, after a lingering illness. He was a surgeon in the German army and received the Iron Cross for skill and bravery during a campaign. A resident of this country for the past twenty years, he achieved more than an average success.

THOMAS J. DOUGHTY, M.D., University of Michigan 1896, Health Officer of Fishkill and Matteawan, N. Y., died at the home of his father, Dr. John H. Doughty, August 2. He was aged about 31 years.

WARREN KEMBLE, M.D., College of Physicians and Surgeons, N. Y., 1868, of Saugerties, N. Y., died there August 10, aged 57 years.

E. GERTRUDE CRUM, M.D., Assistant Physician of the Binghamton (N. Y.) State Hospital for the Insane, died August 5, aged 31 years.

JOHN H. BAILEY, M.D., Sturgis, Ky., July 30, aged 28 years.

—FRANK HAMER BRICKELL, M.D., New Orleans, La., August 8, aged 41 years.—WILLIAM MCGREGOR, M.D., of the McGregor Hospital, Sioux City, Iowa, August 5.—J. D. MARTIN, M.D., Savannah, Ga., August 3, aged 40 years.—E. G. MOORE, M.D., Spring Valley, Ill., August 11.—AMBROSE MORRISON, M.D., Nashville, Tenn., August 3.

BOOK NOTICES.

Wounds in War. The Mechanism of their Production and their Treatment. By Surgeon-Colonel W. E. STEVENSON, Professor of Military Surgery, Army Medical School, Netley, England. Pp. 588. Svo, profusely illustrated. New York: William Wood & Company. Muelin, \$4.00 net.

The author says truly in his preface "that no branch of surgery has undergone more important changes in consequence of the teachings of Lister and Pasteur than that of gunshot wounds."

There are fourteen chapters, divided as follows: 1. Introductory remarks on wounds by side arms, rifles, portable firearms and the mechanics of projectiles. 2. Characteristics of injuries produced by projectiles. 3. The primary phenomena and symptoms accompanying gunshot wounds (such as shock and hemorrhage). 4. Treatment of wounds in war. 5. General treatment of the bullet wounds. 6. Gunshot wounds of joints. 7. Gunshot wounds of hip-joints. 8. Gunshot wounds of the diaphyses of long bones. 9. Wounds of the head. 10. Wounds and injuries of the chest. 11. Wounds and injuries of the abdomen. 12. Injuries of the pelvis. 13. Defects and use of modern small arms in the wars of the future. 14. The Geneva Convention.

The illustrations in the volume comprise a good many photographs showing the effect of gunshots. The recognition of American authors is full and complete, the lamented Otis being frequently quoted and at length. Senn, Nancrede, McGraw, Marion-Simms and the late Charles T. Parkee are mentioned frequently. In regard to Otis the writer says: "I have frequently availed myself of that inexhaustible source of information on this subject, 'The Surgical History of the War of the Rebellion' in the United States, by G. A. Otis, a work which must continue to be a record of labor and research which may never be surpassed." Notwithstanding the generous praise given by the author to his predecessors, he has ample reason for having opinions of his own on most subjects and indeed does not hesitate to modestly express them.

The author points out the infrequency of amputations in these latter days, but our military brethren will see nothing about the effects of the Mauser bullet, although there is an abundance of material on others of the same class.

The work is of great value, not only to military but to civil surgeons as well.

Manual of the Diseases of Children. By JOHN MADISON TAYLOR, M.D., and WILLIAM H. WELLS, M.D. Illustrated. Pp. 473. Philadelphia: P. Blakiston's Sons & Company, 1898. Price \$4.00 net.

This is not claimed to be an exhaustive treatise on the dis-

eases of children, although if it had been so claimed, the claim would not have been far out of the way, as it seems to contain all the essentials, and the aim of the authors has been to present in a clear and precise manner the chief points. Pathology has been abbreviated, not because this most important division of the subject is not valuable, but for the reason that in so small a work there is not surface room to adequately describe the constantly increasing discoveries in this direction.

There are twenty chapters which cover in a general way the physiology of the infant in childhood; diseases occurring at or near birth; general hygiene of infants and children; feeding and food; the breeds of cows best adapted for infancy feeding; diet of children; artificial foods, recipes, etc.; diseases of the peritoneum; diseases of the liver, diseases of the genito-urinary system; diseases of the genital organs; diseases of the blood; diseases of heart, respiratory organs; nervous system; diseases of the acute infections; diseases of the skin; physical development; diseases and accidents requiring surgical procedures. The book is well written and up-to-date.

International Clinics. A Quarterly of Clinical Lectures. By JUDSON DALAND, M.D.; J. MITCHEL BRUCE, M.D.; DAVID W. FINLEY, M.D. Volume ii, 8th series. Pp. 363. Philadelphia: J. B. Lippincott Company. 1898.

These clinics are very useful and the present volume contains clinical lectures on subjects of current interest to the profession. The contributors to the volume are A. H. Free-land Barbour, M.D.; A. L. Benedict, M.D.; S. S. Bishop, M.D., B.S., LL.D.; William C. Boteler, M.D.; James Cantlie, M.B., F.R.C.S.; J. H. Claiborne, M.D.; Henry Clark Coe, M.D.; E. Treacher Collins, F.R.C.S.; Floyd M. Crandall, M.D.; Charles Green Cumston, M.D.; James Mackenzie Davidson, M.D.; Prof. C. A. Ewald; L. Webster Fox, A.M., M.D.; Louis Frank, M.D.; J. McFadden Gaston, M.D.; A. Pearce Gould, M.S., F.R.C.S.; Professor Grancher; J. N. Hall, M.D.; B. C. Mirst, M.D.; W. W. Keen, M.D.; John A. Larrabee, M.D.; Alexander McPhedran, M.D.; W. Milligan, M.D.; F. W. Mott, M.D.; T. Pickering Pike, F.R.C.S.; A. Pinard, M.D.; Prof. Albert Robin; A. D. Rockwell, M.D.; William L. Rodman, M.D.; J. T. Schamberg, M.D.; N. Senn, M.D.; John Lindsay Stevens, M.D.; Prof. R. Von Jaksch; W. Hale White, M.D.; Frank C. Wilson, M.D.; James K. Young, M.D.

It will be seen by the list of names and the special articles by each, that medicine, neurology, surgery, gynecology, obstetrics, ophthalmology, laryngology, pharyngology, rhinology, otology and dermatology have able representatives. As clinicians the ability of these teachers is well known, and the fortunate possessor of this book, if he draw on his imagination very little, can easily imagine himself once more in the amphitheater reviewing the scenes but not the teachings of his youth. The popularity of these volumes has been immense and it is not likely that there will be any falling off in the interest which attaches to them.

The Office Treatment of Hemorrhoids, Fistula, etc., without operation, together with remarks on the relation of diseases of the rectum to other diseases in both sexes, but especially in women, and the abuse of the operation of colostomy. By CHARLES B. KELSEY, A.M., M.D. 12mo, cl. 68 pages. Price 75 cents, net. New York. E. R. Pelton, 1898.

The contents of this volume are: The Cure of Hemorrhoids, Fistula, Fissure and other Affections of the Rectum by Office Treatment without Operation. On the Relation between Diseases of the Rectum and other Diseases in both Sexes, but especially in Women. On the Abuse of the Operation of Colostomy, or the Formation of an Artificial Anus.

Anything written by Doctor Kelsey on subjects with which he has been so many years identified will always receive attention. Doctor Kelsey has proved that a great many cases of hemorrhoids and fistula can be treated without surgical operation and this little book contains three lectures that set forth

his methods. The charlatan has too frequently had a monopoly of operations "without the knife or ligature," and the author has done well in giving the legitimate profession the means of accommodating those of their clients whose fear of operative measures is likely to lead them astray.

Electricity in the Diagnosis and Treatment of Diseases of the Nose, Throat and Ear. With 16 illustrations. By W. SCHEPPEGRELL, A.M., M.D. Pp. 403. New York and London: G. P. Putnam, Sons, 1898 [from A. C. McClurg & Company, Chicago]. Price \$4.50.

The illustrations in this book are fair, and the printing is well done. The book is printed on good paper.

The use and application of electricity has been retarded largely by reason of the extravagant claims made for it at the outset. These have now become circumscribed and the exact field of electro-therapeutics more clearly defined. In effect, while the claims have become more trustworthy, the use of electricity in medicine has become greatly extended and it is believed now by many, that, so far as electro-therapeutics is concerned, notwithstanding its occasional brilliant results, it is now only on the threshold of what it will become in the future.

Exercises in Practical Physiology. By AUGUSTUS D. WALLER, M.D., F.R.S. Part 3. Physiology of the Nervous System; Electro-Physiology. Pp. 80, 91, bds. London: Longmans, Green & Company. 1897.

We have already noticed the first and second parts of this physiology, and this volume is a continuation of the series and gives full directions for the carrying out of experiments in the physiologic laboratory on the physiology of the nervous system. There are sixty-eight demonstrations in this work.

Atlas and Epitome of Operative Surgery. By Dr. OTTO ZUCKERKANDL. Authorized translation from the German. Edited by J. CHALMERS D'ACOSTA, M.D. With 24 colored plates and 217 illustrations in the text. Pp. 395. Philadelphia: W. B. Saunders. 1898. Price \$3.00 net.

This Atlas is a valuable one. The selections are judicious. This book is a very fitting companion piece to the surgery of the translator, which was issued about the same time and which is elsewhere noticed.

Tropical Diseases, A Manual of the Diseases of Warm Climates. By PATRICK MANSON, M.D., LL.D. (Aberd.), London. Pp. 625. 12mo. Illustrated by 88 wood engravings and two colored plates. New York: William Wood & Company. Muslin, \$3.50 net.

Dr. Patrick Manson, the author of this book, has had a special opportunity for observation of the tropical diseases, especially in China, where his various papers have been published from time to time in the medical reports of the *Imperial Chinese Customs Gazette* and have been of great value and peculiar interest. To Manson is due, more than to any other, the establishment of the fact that the mosquito is the intermediate host of the *filaria nocturna*. Few have had better opportunities for observation of the filarial diseases than Dr. Manson, and he has made very good use of them.

A careful review is given, in the book, of the unclassified fevers of the tropics. Beriberi, leprosy and yaws receive full attention.

Just now, when the eyes of many medical men are turned toward the tropics, this volume will prove very interesting and instructive.

A Practical Treatise on the Diseases of Women and Their Treatment by Electricity. Third edition, revised, rewritten and greatly enlarged. By G. BETTON MASSEY, M.D. Illustrated with twelve full-page original chromo-lithographic plates in colors, numerous full-page original plates of photographs taken from nature, and many other engravings in the text. Royal octavo, 400 pages. Extra cloth, beveled edges, \$3.50 net. New York, Philadelphia and Chicago: The F. A. Davis Company. 1898.

The work of Dr. Massey as completed gives a fair résumé of the teachings of the day in regard to the use of electricity in gynecology. It will be especially welcomed by those who limit

the field of operative surgery in gynecologic cases, in some of which electricity sometimes exerts a wonderful influence. Heretofore the electricians have seemed to claim too much for their favorite agent. That it has a distinctly enlarging scope there is no doubt. The work under consideration is conservative and well written.

A Primer of Psychology and Mental Diseases for the Use of Training Schools for Attendants and Nurses and in Medical Classes. By C. B. BURR, M.D. Second edition, thoroughly revised. Pp. 116. Philadelphia, New York and Chicago: The F. A. Davis Company, 1898.

This book is a general guide to the management of cases of insanity, and contains also a valedictory address delivered to the class of 1895, Training School for Attendants of the Eastern Michigan Asylum. It is well adapted for the use of junior medical students as well. In the management of cases the author's advice is sound and judicious. Many of the precepts laid down by him are worthy to be engraved over the doors of the wards of asylums so that they might be ever present to the attendant.

A Manual of Surgery for Students and Practitioners. By WILLIAM ROSE, M.B., B.S. Lond., F.R.C.S., and ALBERT CARLESS, M.S. Lond., F.R.C.S. Pp. 1162. 8vo. Profusely illustrated by wood engravings. New York: William Wood & Co., Publishers. Extra muslin \$5.00 net, leather \$5.75 net.

This work is intended to be a complete treatise on surgery, in a single volume, and its principal author is well known in this country as a distinguished operator. We have examined this book with much pleasure and take pleasure in commending it. We recognize a number of old-timers among the illustrations, but for the most part they are new. We commend the work and predict for it considerable popularity in this country.

Manual of Physical Diagnosis, for the use of students and physicians, by JAMES TYSON, M.D. Third edition, revised and enlarged. Colored and other illustrations. Pp. 179. Philadelphia: P. Blakiston's Son & Company, 1898. Price \$1.50 net.

This manual has not been changed especially from the last edition except in the sections on examination of the blood and the chemic examination of gastric contents. A number of new illustrations have been introduced together with other additions of a minor character, all adding to the accuracy and usefulness of the book.

Prof. Tyson is too well known as a careful observer and skillful clinician for us to do more than mention his name in connection with a work, to give it sufficient praise.

Ovariotomy and Abdominal Surgery. By HARRISON CRIPPS, London; J. & A. Churchill, 1898. [Philadelphia: P. Blakiston's Son & Company. Price \$8.00 net.]

The author says, "the chief object of this work is to record only such operative details as I have found valuable in my experience, that without the book running into a larger scope than was intended, it is impossible to describe in detail the various methods adopted by other operators." Cripps has been known in this country many years, by reason of his bold and original methods of operating. Cases are given in the latter end of the book, and the operator who follows Cripps' methods will make few mistakes.

Manual of Modern Surgery. General and Operative. By JOHN CHALMERS D'ACOSTA, M.D. With 390 illustrations. Pp. 911. Philadelphia: W. B. Saunders. 1898 [From W. T. Keener, Chicago Agent].

This is a much better book than its predecessors. It will be found concise and entertaining, as the book is not padded, but contains the essentials of the practice of surgery. The methods recommended are up-to-date.

Accessory Nipples.—Accessory nipples were noted in 10,000 out of 115,000 recruits examined recently in Germany, according to a communication in the *Progrès Médical* of June 25.

MISCELLANY.

Inherited Tabes. Kalischer reports simultaneous cases of tabes dorsalis in mother and son of 21 years, without a trace of syphilitic antecedents in either.—*Berlin Klin. Woch.*, No. 18.

Cholera in India.—Between Monday morning and Friday night, says a dispatch from Madras, August 13, there were fifty-five deaths from the disease, the fatalities prior to the day first mentioned having been 117.

The School of Medicine of Georgetown University, Washington, D. C., is now a full-fledged day-school, the last evening classes being held last year. On August 15 the new hospital, under the control of the school and having accommodations for thirty patients, was opened, in connection with which there is an emergency and dispensary service.

Moderate Bullet Wounds.—"The destructive character of the bullets when they strike a hard surface, was shown in the wounds treated during the recent riots in Milan," states the *Klin. Therap. Wochenschrift* of June 26. "Every arm or limb wounded had to be amputated; every person shot in the trunk died, and whenever the skull was struck, the top was lifted up like the cover of a box and the brain matter scattered around."

Creation of an Articulation.—Ollier reports unexpectedly successful functional results in a case in which the upper end of the humerus and scapula had already been removed. He created an articulation by fastening the clavicle to the floating upper end of the humeral diaphysis, modifying with a few stitches the points of insertion of the deltoid and scapula muscles to adapt them to the new articulation, which works remarkably well.—*Echo Méd. du Nord*, June 19.

An International Leprosy Archiv.—A leprosy archiv is to be established by a committee including E. Beasner, K. Dehio, A. Hansen, J. Hutchinson and A. Neisser. It is intended to contain all administrative and legislative measures in regard to leprosy as well as scientific communications in the three principal languages. The sympathy and cooperation of all interested in the subject are most cordially requested.

Travelling Professorships.—An anonymous benefactor has presented the Paris University with funds sufficient to endow for a term of years five of the professors "agrégés of secondary instruction" with 15,000 francs each for a trip around the world, a knowledge of English the only condition. Another endowment provides an income of 2,000 francs to be loaned to needy French or foreign students, the amount to be returned later without interest.

Cerebral Neoplasms.—Krauss in the *New York Medical Journal* for July 30, considers the classic symptoms of brain tumor in their order of importance as: 1, head pain; 2, optic neuritis; 3, mental apathy; 4, nausea and vomiting, and 5, paralysis as a special localizing symptom. The early symptoms are headache, incapacity for mental work, disordered digestion, nervous irritability, and a general malaise. Choked disc or optic neuritis he considers almost pathognomonic of cerebral tumor and a decisive symptom.

Alcohol Injections in Cancer.—In the *Philadelphia Medical Journal* of May 28, Kuh makes a second contribution to this treatment. He reports cases and discusses the work of Haese of Germany, in curing fifteen out of eighteen well authenticated breast cancers. He believes one may safely begin with 30 per cent. injections, increasing to 40 or 50 per cent., as the tolerance of the patient permits. He says that in cases in which the growth has become adherent to the pectoral muscle, Haese always advised the operation, followed by alcohol injections, and again, all relapses should be treated or prevented by the injection method, as the pitiful insufficiency of surgery in relapses is too well known to be dwelt upon.

"**Journal of Tropical Medicine.**"—It is proposed, if enough support can be obtained for the scheme, to publish in London a monthly journal dealing with the diseases of warm climates, to be devoted to the publication of papers on tropic diseases and to the discussion of subjects scientific and practical affecting the interests of medical men in tropic and subtropic climates. The annual subscription, including postage, is to be 17s. We wish the promoters success in their new venture. They deserve it, for there is no country which has such a large interest in the tropics and the diseases common to them as our own.

Longevity and Wine.—According to *La Médecine Moderne*, red wines are preferable to white because the consumers of the former live longest. A viticulturist of the Gironde bethought himself to carry out an investigation as to human longevity in white and red wine districts respectively, taking as his basis the electoral lists in the various departments. Among 7738 electors domiciled in a red wine country he found 381 individuals who were more than 75 years old, whereas among 3029 electors belonging to a white wine country there were only eighty-one, an appreciable difference. Yet red wine is more easily adulterated than white wine.—*London Lancet*, July 16.

Recovery from Traumatic Tetanus.—Davis (*Annals of Surgery* for August) reports two cases of recovery from traumatic tetanus after the use of antitoxin. The first case received forty-two doses in eighteen days, the second twenty eight in twelve days. Sedative drugs were used in addition to the antitoxin, but he believes that this does not destroy the value of the evidence for antitoxin. In the first case symptoms arose one week after its reception and during the next week had not progressed further than having pain in the cheek, throat, back and neck, with contraction of the facial muscles, difficulty in swallowing, inability to fully open the mouth and a slightly staggering gait. The second case on entering the hospital was having three to eight spasms hourly, the injury having been received three weeks previous to admission; and his symptoms had been present for a week.

Epilepsy.—According to the latest views, epilepsy is a complex of symptoms proceeding from a diseased condition of the cortex, induced by three factors; hereditary and personal tendency and a periodically-recurring, exciting cause, evidently toxic substances periodically accumulating in the organism from abnormal metabolic processes. The nature of these toxic substances is still undetermined; in certain cases it seems to be the ammonium carbamate derived from the urea. These views indicate the importance of dietetic and therapeutic measures to control the metabolism and promote the elimination of the toxic substances, while they still maintain the value of the bromids and quieting remedies. They also point out the lines for further research.—*Munich Med. Woch.*, June 28.

Endarteritis of the Renal Arteries.—Drs. Bradford and Lawrence have made a joint research on this subject and report an illustrative case in a hospital patient, a female, aged 36 years, suffering from anuria: history mainly negative; anemia and weakness, but no dropsy, headache, sickness or convulsions; intellect clear to the last. The cortex of each kidney was found bright buff-colored, and sharply defined from the pyramids; microscopically the convoluted tubules were seen to be necrotic. This necrosis was due to thrombosis of all those branches of the renal artery which had reached an approximate diameter of 100 μ evidently of the so-called "interlobular" arteries; all branches of the renal arteries were extensively diseased, the media and especially the intima being thickened and sclerosed. The interstitial tissue of the kidneys was not increased. The patient thus presented the typical clinical picture associated with "obstructive suppression," while the morbid appearances were such as should, according to

theory, have given rise to uremia. The authors hold that this case throws grave doubts on the view held by many, "that uremia is independent of the mere retention of normal but toxic products that ought to be excreted." The case also shows the independence of renal endarteritis and extensive renal cirrhosis.—*British Medical Journal*.

Gunshot Injuries of the Spine.—Prewitt (*Annals of Surgery* for August) divides gunshot injuries of the spine into three classes: 1. Those that simply fracture the arches. 2. Those that invade the canal, crushing the cord and damaging the vertebrae. 3. Those complicated by serious injury to abdominal or thoracic viscera. As to the first class, he advises immediate treatment by laying open the track of the wound under most rigid antiseptics, as do most surgeons. Although most of the second class cases are fatal sooner or later, he believes that the dangers of myelitis and meningitis, with a prolongation of the lives of some, even though paraplegic, will follow the cleaning and disinfecting of the wound. Of the third class he says: "The presence of complications due to the penetration of the great cavities and injury of the viscera will influence the question of operation, but not necessarily forbid it."

Hysteric Joints.—Moore (*Annals of Surgery* for August) writes on "Hysteria from a Surgical Standpoint" and says that it is in joint and spine ailments that the surgeon is most likely to meet with hysteria, and it is of so frequent occurrence here and often so closely resembles the real disease that he must ever be on his guard lest he mistake the shadow for the substance. These hysteric joint affections sometimes so closely resemble tubercular joints as to deceive very good diagnosticians, and usually follow an injury. While there may be slight atrophy, it is only that due to non-use or bandaging. There is no rise of temperature, though it may be subnormal, and while there may be slight puffiness about the joint, there is no marked swelling. The restriction of motion is different from that characteristic of tuberculosis, varying from one moment to another and even temporarily disappearing when the patient's attention is directed elsewhere. The muscular spasm is very different from that of tuberculosis, it being more marked and voluntary. The hysteric joint is usually deformed and the deformity often greatly exaggerated. The deformity is apt to be a flexion. As a treatment he has obtained the best results by reducing the deformity, holding the limb in proper position for a short time and insisting that a cure has been wrought, very little anesthetic being necessary.

Pulmonary Tuberculosis.—Stubbert (*New York Medical Journal* for July 30) in discussing "Sanitarium Treatment of Pulmonary Tuberculosis," says that the cured incipient cases are estimated at 59 per cent., statistics being compiled under the most favorable circumstances obtainable in properly conducted sanitariums. He considers the first essential in a sanitarium a routine examination in all details, basing treatment upon climatic, hygienic and dietetic influences. He considers diet an all-important factor and increase of weight a prognostic factor of great importance. At the Loomis Sanitarium all patients, unless temporarily excused, are required to remain out of doors eight hours a day, and within a month after arriving the majority of their patients are able to walk from one to seven miles a day and they do it. The room temperature is not allowed to be over 65 degrees during the day and all windows are left open at night. As to the advantages of serum treatment, he says: "1. It does not tax the function of digestion or produce gastritis, diarrhea or loss of appetite. 2. In cases wherein the bacilli have disappeared, they have been lost while sputa were still present, whereas in creosote cases the last specimen of sputa contained bacilli. 3. Up to the present time no relapses have occurred among our patients declared cured by serum treatment; they are occasion-

ally met with in creosote cases." The writer claims to treat about an equal number of patients with tuberculosis, in the sanitarium and out of it, and from his experience has found that all incipient cases do better within a sanitarium, *i. e.*, one built on the cottage plan; a smaller percentage do well outside. Statistics show that about 86 per cent. treated in a sanitarium improve, but only 58 per cent. outside, and that in 41 per cent. the disease is arrested and cured within, but in a less percentage outside. In far advanced cases he believes the patients are better off at home.

Defective Compensation in Heart Troubles.—Defective compensation in heart troubles is best remedied, according to the experience of Prof. H. Eichhorst of Zurich, with a combination of digitalis and diuretin (double salicylate of sodium and theobromin). It is indicated in every case, he states, that is not cured by absolute repose. A course of thirty powders will completely cure the edema and concomitant disturbances in nearly every case. There is sometimes a peculiar somnolence, with dyspnea and psychic troubles, but these are caused by the absorption of the edema and not by the medication, and subside as the noxious substances are gradually eliminated through the kidneys. Formula: pulverized digitalis leaves, 10 centigrams; diuretin, 1 gram; sugar, 30 centigrams. For one powder. Make xii. Take three a day after meals.—*Semaine Méd.*, June 29.

Insomnia.—In the *Maryland Medical Journal* of July 23, Bond writes on "The Therapeutics of Insomnia," defining insomnia as "Any deficiency in sleep which threatens to interfere with health." He considers too shallow sleep with dreaming, or a sleep that leaves one tired on waking, forms of insomnia, and believes that testimonials of the sleeper as to how much he sleeps are necessarily questionable; therefore the first thing in the treatment is to find out whether insomnia is really present. In either case treatment must be given, in the former, tonics until the patient forgets his alleged insomnia, in the latter, hypnotic agencies. He says: "The physician's duty is not so much to compel as to secure permission for sleep. The hindrances to sleep proceed usually not from the brain itself, but from a disorder of the blood, and this usually from abnormal processes in the kidneys and other excretory organs and in the digestive tracts, or perhaps from the inhalation of impure air. . . . Although it is very dangerous to prophesy limitations to the progress of any science, yet I may venture to say that progress in hypnotic therapeutics will be along the line, not of a discovery of a universal ideal hypnotic drug, but of a more thorough study of the varying conditions in insomnia and of the circumstances which favor or hinder the effect of each drug."

Management of the Tuberculous Insane.—Dr. Bracken, Secretary of the State Board of Health of Minnesota, writes on the above subject warmly recommending a larger adoption of the principle of isolation at hospitals for the insane of tuberculous patients, and says further: "The greatest scourge of these institutions is tuberculosis, and there is a certain degree of apathy among physicians having charge. They do not recognize the etiologic relation between phthisis and insanity. I am convinced, however, that such causative conditions can be shown in not a few hospitals. The American Public Health Association has, by the report of its Committee on Restriction of Tuberculosis, pointed out the means of limiting the spread of this disease. By the adoption of these means the percentage of tuberculous deaths to the general death rate in one hospital has been reduced in the course of three years from an average of 25 per cent. to a fraction under 9 per cent. I was interested in this hospital report from Dr. Rohé of the Maryland hospital at Catonsville, and wrote to Dr. Wade, his successor, to learn the present condition of the tuberculous patients. He informs me that the death-rate from tuberculosis for 1896 was but 6.1

per cent. Dr. Wade describes the manner of caring for the tuberculous insane in this hospital as follows: "The sputa of the suspected case is examined, and if the bacilli are found the patient is placed in a single room, the walls of which are painted and can be easily disinfected. The furniture consists of an iron bedstead, which is readily cleaned. There are no curtains to the windows and no carpet upon the floor. The patient is persuaded, if possible, to expectorate into a vessel, which is disinfected with mercuric chlorid. If the patient expectorates about the room no harm can be done, however, as everything can be readily washed with a disinfectant. The bedding is properly cared for and is used for no other bed. After the death of the patient, the room and all of its contents are thoroughly disinfected."—Transactions Conference of State and Provincial Boards of Health.

Diet for the Sick in Army Hospitals.—So much has been published in the daily press about the unsuitability of the army ration as a dietary for sick soldiers, that the War Department has practically freed the kitchens of general hospitals from any need to rely on the coffee, hard bread and bacon of the ration. Up to this time the hospitals were entitled to one ration per day for each patient. Such articles of the ration as were required for use were drawn from the Subsistence Department in kind, and the money value of the articles not drawn was available as a hospital fund for the purchase of other articles of food from the Subsistence Department or from outside parties. General orders just published authorize surgeons in charge to expend 60 cents a day per patient for the subsistence of the sick in their wards. This is simply a commutation of the ration as a whole instead of the commutation of that part of it not drawn in kind; but as the new orders commute the ration at a much higher figure than its actual value, it gives ample facilities for providing all sorts of delicacies for the sick and for rendering them independent of the charity of the various relief associations. The orders are as follows: Medical officers in charge of general hospitals, hospital trains, hospital transports and the hospital at the camp at Pablo Beach, Florida, and at the hospital at the camp at Montauk Point, New York, will be allowed to expend from the appropriation "Subsistence of the Army," for the diet of the enlisted men undergoing medical treatment under their charge, at the rate of not exceeding 60 cents per man per day for the period each is undergoing treatment. The allowance so made will constitute a special fund in the hands of the medical officer in charge, from which will be purchased the entire diet of the enlisted men while undergoing medical treatment. These purchases will be restricted to articles of food, solid and liquid, the quantities and varieties of which will be determined by the medical officer in charge. Chief commissaries of departments will transfer to medical officers in charge such subsistence funds as may be estimated for by the latter for carrying out the objects of this order. There will be rendered monthly to the Commissary General of Subsistence, by the medical officers concerned, regular accounts current supported by vouchers showing the application of these funds, and regular returns of subsistence stores accounting for the articles of food purchased and issued. There will be submitted with each monthly return a tabular statement showing the number of patients present during the month as shown by the hospital records, and the money value of the articles issued to and consumed by them. The statement will be so arranged as to show the actual cost of subsistence per man per day for the month. Transfers of subsistence funds from one hospital, train or transport to another without authority of the Commissary General of Subsistence, and the purchase from subsistence funds of articles other than food intended for diet of the sick are prohibited. This order will go into effect at once, and all surplus funds in the hands of medical officers in charge, arising from the commutation of rations heretofore allowed to enlisted men undergoing treatment under their charge, will be taken up on their accounts current for the month of August, and all articles purchased from such commutation remaining on hand unconsumed on receipt hereof will be taken up on their return of subsistence stores for that month.

Medical Supplies Recommended to Regiments.—Memorandum of recommendation of Surgeon-General, April 15, 1898, to the Adjutant-General: Each regiment to take two ambulances, four extra litters, a field hospital for ten men, medical and surgical chests, field supplies for three months. Infantry regiments to have a steward or acting steward and ten privates of hospital corps. Cavalry regiments to have two stewards or acting stewards and fifteen hospital corps men. A light battery to have one ambulance, field hospital for five men (one hospital tent), an acting steward and five privates of the hospital corps.

April 20, 1898, the Surgeon-General sent instructions to Major B. F. Pope, chief surgeon, Tampa, Fla., directing him to inspect the medical department of each regiment upon its arrival, and report to him the deficiencies in medical supplies.

CONSOLIDATED LIST OF MORE IMPORTANT ARTICLES SENT TO TAMPA AND SANTIAGO.

First aid packets	No.	39,000
Alcohol	Qt. bottles	3,502
Bicarbonate of soda tablets	No.	237,200
Calomel and soda tablets	No.	40,000
Camphor and opium pills	No.	188,000
Castor oil	Qt. bottles	1,422
Chloroform	0.2 lb bottles	3,470
Compound cathartic pills	No.	259,200
Edher's solution	0.2 lb tins	3,290
Morphine tablets	Oz. bottles	1,180
Quinin pills	No.	17,300
Strychnin tablets	No.	4,678,000
Subnitrate of bismuth	No.	50,000
Antiseptic tablets	lb bottles	657
Carbolic acid	No.	150,000
Iron, sulphate, commercial	2 lb bottles	6,000
Lime, chlorid	20 lb boxes	500
Sulphur, in rolls	lb bottles	4,456
Formal gas generators, with supplies for same	lbs.	4,000
Beef extract	0.2 lb tins	5,790
Brandy	Qt. bottles	977
Condensed milk	tins	3,546
Soap, castile	lbs	974
Soups (Franco-American), 24 cans in case	Cases	981
Sugar, white	lbs	2,868
Tea	lbs	495
Whisky	Qt. bottles	1,621
Stationery, a large supply to cover needs		
Bandages, gauze, sterilized, 144 in box	Gross	839
Cotton, absorbent	lbs	1,240
Gauze, sublimated	Pkgs.	33,000
Gauze, iodoform	"	3,650
Ligatures, catgut, sterilized	"	18,600
Ligatures, silk, sterilized	"	18,600
Oakum	lbs.	1,260
Spouges, compressed cotton	Boxes	2,850
Thermometers, clinical	No.	211
Blankets, gray	"	5,440
Chairs, arm, folding	"	235
Chairs, small, folding	"	2,350
Cots, folding	"	4,250
Mattresses	"	2,500
Mosquito bars	"	3,750
Pillows, feather	"	850
Pillows, hair or cotton	"	4,250
Pillow cases, cotton	"	7,700
Sheets, cotton	"	10,000
Shirts, cotton	"	4,750
Tables, mess, folding	"	235
Tables, bedside, folding	"	2,350
Litters	"	630
Litter slings	"	975
Table and kitchen furniture, for field hospitals	for	3,000
Test tubes	No.	1,540
Medical sets, chests Nos. 1 and 2, each	"	29
Surgical sets, chests Nos. 1 and 2, sterilizer chest and filter, each	"	21

NOTE.—The regular regiments had each a medical and surgical chest, litters and other field supplies before the above articles were issued.

Societies.

The following recent meetings are noted:

- Connecticut.**—New Haven Medical Association, August 3.
Illinois.—Douglas County Medical Society, Tuscola, August 4; Stephenson County Society of Physicians and Surgeons, Freeport, August 4; Vermilion County Medical Association, Danville, August 9.
Indiana.—Shelby County Medical Society, Shelbyville, August 8; Vigo Medical Society, Terre Haute, August 4.
Iowa.—Council Bluffs Medical Society, August 10.
Kansas.—Topeka Academy of Medicine and Surgery, August 8.
Kentucky.—Union County Medical Society, Morganfield, August 1.
Massachusetts.—Berkshire Medical Society, Pittsfield, August 4.
Michigan.—Bay County Medical Society, Bay City, Aug. 15.
Minnesota.—Southern Minnesota Medical Association, Rochester, August 4.
Missouri.—Central District Medical Society of Missouri,

Sedalia, August 4; Jasper County Medical Society, Webb City, August 2; Linn County Medical Society, Meadville, July 26; Putnam County Medical Society, Unionville, August 3.

New York.—Steuben Medical Society, Addison, August 9.
Pennsylvania.—Bucks County Medical Society, Bristol, August 3; Lehigh Valley Medical Society, Allentown, August 9; Luzerne County Medical Society, Wilkes Barre, August 10; York County Medical Society, York City, August 4.

Texas.—Kaufman County Medical Society, Kaufman, Aug. 1.
Wisconsin.—Waupaca County Medical Society, Elwood, August 5.

Philadelphia.

ONSEQUIES OF DOCTOR PEPPER.—The body of Dr. Pepper reached Philadelphia from California August 5, and the remains viewed by only a few intimate friends. On Saturday simple services were held at St. James Episcopal church, the interment being strictly private. The honorary pallbearers were William Platt Pepper, General Isaac Wistar, Edward H. Clark of New York, William Latta, Mayor Charles F. Warwick, Dr. S. Weir Mitchell, representing the trustees of the University of Pennsylvania; Dr. Jonas Tyson, representing the medical faculty of the University; Frederick Fraley, representing the American Philosophical Society; Joseph G. Rosen-garten, representing the Free Library; Ex-Senator George F. Edmunds, representing the Philadelphia Museums; P. A. B. Widener, representing the Philadelphia Exposition Association, and Hampton L. Carson, representing the general alumni of the University of Pennsylvania; Governor Hastings was unavoidably absent. Two provisions of Dr. Pepper's will have been complied with, one of which was that his body be cremated, the other that his brain be given the Anthropological Society of which he was a member, the latter clause being one of the agreements on becoming a member. Among others who have belonged to this society may be mentioned Dr. Joseph Leidy and Phillips Brooks.

SANITARIUM FOR CONSUMPTIVES.—Some time ago the Board of State Charities made a recommendation appropriating \$30,000 for the erection of a sanitarium for consumptives, with the proviso that a like sum be raised by private subscription. Unfortunately this measure never passed the legislative committee rooms. The overcrowded condition of the almshouse in Philadelphia would enlist the sentiment of the members if they would visit it, but this will not probably be done. The Pennsylvania Society for the Prevention of Tuberculosis is again bringing this subject to the front and giving many good explanations of the benefit which would arise from the erection of a building for this purpose. A location has been found in Lucerne County, and offered as a site for the proposed building. A city sanitarium for the treatment of cases of tuberculosis is also being agitated.

BRONZE STATUE TO DOCTOR PEPPER.—The many societies and public enterprises of this city to which Dr. Pepper belonged have all passed fitting testimonials to his memory. Among others may be mentioned the Philadelphia Club, trustees of the Department of Archaeology and Paleontology of the University of Pennsylvania, and a committee of the Philadelphia Museum. Some time before his death the Department of Archaeology and Paleontology of the University decided to erect a testimonial to his memory. This testimonial will now give way to a memorial bronze statue by Bitter of New York, who will also carve the granite foundation on which the statue will rest. The figure represents the doctor in a sitting posture and in a pensive and characteristic attitude.

DR. JOHN GUITÉRAS HOME.—The excessive duties imposed upon Dr. Guitéras while with the army in Cuba finally overcame him and after being in bed for several days with the prevailing fever in the army, he returned home greatly debilitated on August 5. Questioned as to the most serious diseases which threatened the army at the present time, he stated that typhoid and malarial fevers were the worst foes yet encountered. Up to the present time yellow fever had been of a mild

type and but comparatively few deaths had resulted. Regarding the report of differences between himself and the Red Cross Society, he dismissed it by stating that it was absolutely without foundation, and further remarked that "there was only one dispute of importance down there, and that occurred between the Spaniards and Americans."

AN INTERESTING CASE.—It is reported that George H. Wheaton, an employe of Cramp's shipyard, Philadelphia, recently fell from a scaffold, striking on his head and shoulder. Not thinking his injuries serious he remained around the factory for some time but, subsequently, complaining of vague pains, was given permission to go home. After crossing the Delaware river and reaching the opposite shore in Camden he walked for some distance, but became dizzy and was seen to suddenly fall. He died a few minutes later. On subsequent examination at the Cooper Hospital, Camden, there was found a fractured vertebra.

CHARITABLE BEQUESTS.—The following institutions have been made beneficiaries by the will of Jane K. Barclay, who recently died in this city: The Presbyterian Hospital, \$5,000; the Home for Widows and Single Women, \$5,000. By the will of Emily A. Lippincott the following bequests have been made: To the Hospital of the Protestant Episcopal church, \$5,000, an endowment for a free bed; to the Children's Hospital, \$2,500. In addition \$2,500 was also given as an endowment for a perpetual free bed.

STILL WATCHING FOR YELLOW FEVER.—If yellow fever enters this city it doubtless will come by means of railways. The State Board of Quarantine is keeping a strict watch on all lines of boats and steamships which come to this port. A recent resolution was passed to the effect "that on and after August 1, and until further notice, every vessel arriving here from Cape Henry shall be inspected at the Quarantine Station under a penalty of \$500." This city had enough of this disease in 1893.

HEALTH REPORT.—For the week ending August 6, 484 deaths have been reported to the Board of Health. Of these 217 were children under five years of age. Of the total number there is an increase of nineteen over the preceding week and an increase of seventy-two over the corresponding period of last year. Thirty deaths resulted from sunstroke. Infectious diseases: Diphtheria, 29 cases, 10 deaths; scarlet fever, 17 cases, 1 death; typhoid fever, 59 cases, 19 deaths.

SUNSTROKES ARE COMMON.—On July 30 there occurred in this city thirty cases of sunstroke. This is the second largest number recorded this summer, the highest being in the earlier weeks of the month, when forty prostrations occurred. It has been reported by the Weather Bureau that the past few months have been the hottest for thirty years. Two suicides have occurred during the past week, superinduced, it is believed, by the intense heat.

ST. JOSEPH'S HOSPITAL.—While the physicians are off on their vacation, improvements are going on at the St. Joseph's Hospital. New operating, sterilizing and anesthetizing rooms will take the place of the space formerly utilized for this purpose, and when finished it is hoped that the new accommodations will take rank with the best of this city.

Louisville.

KENTUCKY SCHOOL OF MEDICINE.—This college is once more before the public on account of internal dissensions. As recorded in these columns some months ago, the majority of the Faculty declared the chairs occupied by Drs. W. H. Wathen, M. F. Coomes and Henry Orendorf vacant, asking the Board of Regents to ratify its action. After a trial of the charges preferred, the Board refused to concur because of constitutional reasons, and the last session was taught with all three as members of the Faculty. After the conclusion of the term, the majority of the Faculty brought suit in the local court to dissolve the corporation and make the sale of the college property possible. Pending this suit, which was docketed for the October term, the three members, Drs. Wathen, Coomes and Orendorf, declared the chairs occupied by Drs. C. W. Kelly and Sam. E. Woody, also dean, vacant, and their action was

ratified by the Board of Regents, over the protest of the President of the Board, Mr. Jos. P. Helm. Drs. Wathen, Orendorf and Coomes, in the absence of Dr. J. M. Mathews and Dr. J. B. Marvin, who were out of the city, then elected Dr. Sam. Cochran, professor of anatomy, vice Dr. Kelly, and Dr. Arthur G. Boyd (*a graduate from the school in 1896*), as professor of chemistry, and proceeded to elect Dr. W. H. Wathen dean and Dr. H. Orendorf as secretary. Notice was served on the postmaster by both the factions, Dr. Woody, who claims to have been illegally deposed from the deanship, and Dr. Wathen, the new dean, to deliver all mail to them; but the postmaster, complying with the post-office regulations, is holding all mail and marking it "in dispute." Dr. C. W. Kelly is fishing in the northern lakes; Dr. J. B. Marvin and Dr. J. M. Holloway are in Europe, so it is not known what action will be taken.

MATHEWS.—Dr. J. M. Mathews, president elect of the AMERICAN MEDICAL ASSOCIATION, has resigned the position of professor of surgery and lecturer on diseases of the rectum in the Kentucky School of Medicine, and has accepted the same chair in the Hospital College of Medicine, having been elected to the latter position very recently. He will divide the chair of surgery with Dr. H. H. Grant, holding the same title as before in the Kentucky School. His resignation also carries with it membership in the Board of Regents of the Kentucky School. Dr. Mathews states he was led to make the change because of his dislike for such disagreeable occurrences as are now taking place in his former school.

EXECUTIVE COMMITTEE.—The Executive Committee of the Mississippi Valley Medical Association met at the Louisville Hotel on the evening of the 15th, transacting much important business.

ANTHRAX.—Several cases of anthrax have been discovered in a herd of milch cows in the lower end of the city, which has been quarantined by the State Veterinarian. Some action will be taken by the State Board of Health against Indiana, where anthrax is said to be prevalent.

VACATIONS.—The following members of the local profession are away from the city: Drs. J. B. Marvin and J. M. Holloway, in Europe; Drs. L. S. S. McMurtry and C. W. Kelly, among the Canada lakes, fishing; Dr. Wm. Bailey, in Michigan; Dr. J. T. Dunn and Dr. P. B. Scott have just returned from a sojourn in New York City.

COCHRAN.—Dr. Sam Cochran, who recently resigned his position as local Marine Hospital Surgeon, is now lying critically ill with typhoid fever. Dr. Cochran has been making personal attacks upon Dr. C. W. Kelly through his journal, the *Louisville Medical Monthly*, and both he, as editor, and the publisher, have been enjoined by court to cease publication of personalities.

SMALLPOX.—Jackson, Ky., has another case of smallpox, on account of which the Teacher's Institute and the Circuit Court in session, were adjourned. The Board of Health was compelled to build a pest-house on a remote mountain point.

HEALTH BOARD.—The Quarterly report of the Indiana State Board of Health, just published, shows some queer facts. The total number of deaths for the quarter is 3368. Of these only six were caused by phthisis, one by pneumonia; and not a single death from typhoid fever. There were 7165 births, with 3660 males, a decrease in the total number of 667 for a corresponding date last year. There were 160 illegitimate births: 4952 marriages were recorded. 131 of the husbands being under 20 years of age.

NETTLEROTH.—Dr. Alexander W. Nettleroth has just received his commission as assistant-surgeon in the army and has been ordered on duty with the First Army Corps at Chickamauga. He was the second honor man of his class at the Louisville Medical College this year.

MEYERS.—Dr. Sidney J. Meyers has returned from Chickamauga on sick leave of fifteen days, having contracted malaria while on duty there.

FILTRATION.—The Louisville water company has advertised for bids for construction of a filtration plant, which will be opened September 1. This means that Louisville will have within the next year one of the largest filtration plants erected by any municipality. As recorded in these columns, the details of this plant are the results of experiments carried on by several patented methods at the waterworks pumping-station under the supervision of experts employed by the water company. This work consumed about two years, and the plan adopted is the American system, which has received the endorsement of many continental towns of Europe. It comprises the sand process with a quick coagulant; the exact process, however, has not been announced by the company. The new filtration plant will be 24 feet high, 392 feet long and 116 feet wide, built of stone and adorned. The bidders for the

work must give a bond of \$100,000 and they are limited to residents of Louisville and Jefferson County.

LAY OPINION.—The *Courier-Journal*, in commenting editorially on the death of Rear Admiral Kirkland, refers to the surgery in his case as "one of those delicate surgical operations which have become so common within the last few years;" the death of Admiral Kirkland "illustrating the fallibility of medical prognosis;" going on to state that after an apparently successful operation one of the surgeons was quoted as expressing the opinion that the operation was highly successful and most satisfactory, and had it been postponed twenty-four hours the illness would have proven fatal, yet in spite of this the patient sank rapidly and died two days later. It is stated that this is one of so many deaths following operations that eminent surgeons in this country and Europe are lifting their voices in warning against reckless practitioners whose anxiety to perform capital operations prompts them to take enormous risks. After this, and further condemnation of surgeons and surgical procedures, the article concludes with the following words: "That in Admiral Kirkland's case the work was done only upon the most mature deliberation and as a last resort does not alter the truth of all this." From such articles as these and they are by no means infrequent, the laity form their opinion of surgery and refuse any surgical interference even when absolutely demanded.

THE PUBLIC SERVICE.

Movements of Army Medical Officers.—Assigned to duty with the Second Army Corps, Camp Alger, Va.: Acting Assistant-Surgeons Wm. B. Summerall from Atlanta, Ga.; D. T. McKinney from New Brighton, Penn., and Alfred B. Giles from Baltimore, Md. To Ponce, Porto Rico, via Fort Monroe, Va.: Acting Assistant-Surgeon John N. Goltra from Buffalo, N. Y. To General James F. Wade as Chief Surgeon on his Staff: Major J. L. Powell, Surgeon U. S. Army. To duty with troops at Chickamauga Park, Ga., the following acting assistant-surgeons: Geo. G. Morris, Victor E. Watkins and Ernest W. Fowler from Washington, D. C.; O. C. Heiss from Nebraska City, Neb.; Robert L. Bartlett from New York City, N. Y.; Geo. H. Calkins from Tonawanda, N. Y.; Henry B. Stotter from Cleveland, Ohio; Frank E. Crossier from Lebanon, Ohio, and Robert C. Rind from Towson, Md. To duty with troops at Tampa, Fla.: Acting Assistant-Surgeons Thos. C. Avery from Washington, D. C., and Elbert E. Persons from Chicago, Ill. To General Shafter at Santiago, Cuba, via Tampa, Fla.: Acting Assistant-Surgeons Henry H. Bradley from Buffalo, N. Y., and Lewis B. Childs from Washington, D. C. To the Commanding General, camp at Montauk Point, Long Island, N. Y.: Major C. L. Heilmann, Surgeon U. S. Army, and Major Robert Burrus, 1st New Hampshire Volunteer Infantry from Look-out Mountain, Tenn. To the General Hospital at Montauk Point, Long Island, N. Y.: Major Charles S. Nancrede, Brigade Surgeon from 1st Division, 2d Army Corps and Acting Assistant-Surgeons Frank C. Jones from Cleveland, Ohio, Harry C. More from New York City, N. Y., and A. R. Booth from Washington, D. C. To the General Hospital, Fort Thomas, Ky.: Major Wm. R. Hall, Surgeon U. S. Army, from the General Hospital, Key West, Fla., to take charge. To the Leiter General Hospital, Chickamauga Park, Ga.: Acting Assistant-Surgeons B. R. Shurly from Washington, D. C.; W. C. Berlin from Cleveland, Ohio and John H. Alwin from Athens, Ohio. To the General Hospital, Key West, Fla.: Captain Henry A. Shaw, Assistant-Surgeon U. S. Army, from Key West Barracks, Fla. To the General Hospital, Washington Barracks, Washington, D. C.: Acting Assistant-Surgeons Wm. J. Ashby from Alexandria, Va., and J. R. Shannon, whose former orders are revoked. To the Hospital Train at Tampa, Fla.: Capt. H. A. Shaw, Assistant-Surgeon U. S. Army. To the General Hospital at Fort Monroe, Va.: Lieut.-Colonel A. A. Woodhull, Deputy Surgeon-General U. S. Army. To the General Hospital, Fort Myer, Va.: Major Elmer E. Heg, Brigade Surgeon, and Acting Assistant-Surgeon Harold W. Cowper from Buffalo, N. Y. To the General Hospital, Fort McPherson, Ga.: Acting Assistant-Surgeon James C. Ross from Salt Lake City, Utah. To the U. S. Hospital Ship *Missouri*: Major Wm. H. Arthur, Surgeon, U. S. Volunteers, to command. To proceed to their homes: Major Victor C. Vaughan, Surgeon 33d Michigan Vol. Infantry, and Acting Assistant-Surgeon Frank Donaldson. Resigned: Capt. John H. Dickerson, Assistant-Surgeon 9th Battalion Ohio Volunteers.

A Sanitary Order from the War Department.—The following was issued August 10 by the Adjutant-General of the Army:

In order to prevent as far as possible the diseases incident to encampments of large bodies of men, namely: typhoid and malarial fevers, diarrhea and dysentery, and the further spread thereof where these diseases have already gained more or less headway, all officers, from the commanding general to company commanders, will exercise the utmost vigilance to enforce proper sanitary conditions in camp and strict cleanliness of the person.

The speedy destruction or removal with safety of all decaying substances present and future, and the rendering innocuous the feculent matter of the camp, must be accomplished.

The Quartermaster's Department will furnish lumber for floors to all tents. The general commanding camp will at once provide ample hospital facilities by erecting barracks where there is a shortage of hospital tents.

No effort will be spared to carry this order into effect to the fullest extent, and to this end those concerned will not rest content with the issuance of orders upon the subject, but they or their representatives, duly impressed with this grave responsibility, will immediately see to the

commencement, continuance, superintendence and practical accomplishment, day by day, of the instructions imposed upon the command.

The attention of all concerned is called to Army Regulations concerning interior economy, police, and discipline of companies, to Circular No. 1, Surgeon-General's Office, April 25, 1898, to "Marches" and "Camping" in the authorized Drill Regulations, to "Soldier's Handbook" and the remarks therein compiled. From these easily accessible data, supplemented by his own practical experience and that of others, the commanding general of each camp will at once prepare and put into immediate execution a simple code of rules, of the daily practical accomplishment of which he will assure himself, rendering daily reports to the Adjutant-General of the Army.

By order of the Secretary of War.

H. C. CORBIN, Adjutant-General.

Promotions in the Marine-Hospital Service.—Passed Assistant-Surgeons to be Surgeons: Cyrus T. Peckham, Aug. 10, 1898; Arthur H. Glennan, Aug. 10, 1898; Eugene Wasdin, Aug. 10, 1898; Stephen D. Brooks, Aug. 10, 1898; Joseph H. White, Aug. 10, 1898.

CHANGE OF ADDRESS.

Bell, J. W., from 2361 to 2301 S. Bryant Av., Minneapolis, Minn.
Bleeh, G., from 6236 Sangamon St. to 1443 Michigan Av., Chicago.
Behle, W. H., from Blackfoot, Idaho, to Summit Blk., Salt Lake City, Utah.
Campbell, T. F., from Springfield, Neb., to Fairfax, S. D.
Cleveland, C. C., from 1215 W. 23d St. to 1215 W. 33d St., Minneapolis.
Emmerson R., from Chicago to care of Mexican National R. R., San Luis Potosi, Mexico.
Gibben, J. H., from Philadelphia, Pa., to Jefferson Barracks, Mo.
Hatfield, M. P., from Col. Menz Bldg., to R. 400 Reliance Bldg., Chicago.
Hodges, F. J., from Anderson, Ind., to Ashland, Ohio.
Huecker, Jr., from Ferguson Bldg. to 700 15th St., Denver, Colo.
Herr, A. W., from Woodburn, Iowa, to Battle Creek, Mich.
Hill, W. H., from New Castle, Mo., to Gentryville, Mo.
Hertzle, D., from 2314 Montgomery, to 112 E. College St., Louisville, Ky.
Jaquith, W. A., from 1184 Wilcox Av., to 1375 W. Harrison St., Chicago.
Klasen, J. P., from Chicago to Huron, Ohio.
Kempker, J. F., from Des Moines to Houghton, Iowa.
Lesan, C. T., from Bedford to Mt. Ayr, Iowa.
Manson, S. E., from Mt. Pulaski to Rochester, Ill.
Morgan, R. G., from 234 N. Penn. to Ind. Med. Coll., Indianapolis, Ind.
Minard, E. J. C., from Brooklyn, N. Y., to Chicago, Ill.
McCreery, R. L., from University Park to 133 Grant Av., Denver, Colo.
Maclean, D., from Detroit, Mich., to Hotel Chamberlin, Fortress Monroe, Va.
Patterson, H. A., from Brayfield to Downing, Ill.
Pinto, A. S., from Omaha, Neb., to 3d Div., Hospital, Panama Park, Fla.
Prather, D. J., from Oakland to Gen. Del. Sacramento, Cal.
Plummer, R. W., from Mt. Vernon, Ill., to Tyrone, Pa.
Runde, F. W., from St. Louis, Mo., to Room 9 McClintock Blk., Denver.
Sandow, B. F., from Meihart, to Helena, Mont.
Schauffler, E. W., from 800 Main St. to 1220 Washington St., Kansas City, Mo.
Stevens, A. M., from Ann Arbor, Mich., to 143 E. Berry St., Ft. Wayne.
Southard, W. F., from 603 to 1220 Sutter St., San Francisco, Cal.
Stone, C. A., from Weldon to Mason City, Ill.
Smolt, C. F., from Newton to Ottawa, Kas.
Savage, G. H., from Nashville, Tenn., to Sherman, Texas.
Thoms, S. J., from Ann Arbor to Corey, Mich.

No. 9.

ORIGINAL ARTICLES.

A CONTRIBUTION TO THE STUDY OF THE SYMPTOMS OF CHRONIC URETHRITIS.

Presented to the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo. June 7-10, 1898.

BY FERD. C. VALENTINE, M.D.

PROFESSOR OF GENITO-URINARY DISEASES NEW YORK SCHOOL OF CLINICAL MEDICINE; GENITO-URINARY SURGEON WEST SIDE GERMAN DISPENSARY; GENITO-URINARY CONSULTANT UNITED HEBREW CHARITIES, ETC.
NEW YORK, N. Y.

The fact that a patient observes a persistent or occasional drop at the meatus, by no means proves that gonorrhea exists. On the other hand, the absence of discharge does not exclude the presence of chronic gonorrhea. This fact alone warrants a detailed study of the symptoms of this disease.

At the outset, it is well to say that no attempt at considering the urethritides in general is made. To extend this paper to the urethritides of a non-gonorrheal character would expand it beyond its intended dimensions. Moreover, the urethritides, other than gonorrheal, merit exhaustive study by themselves.

The separate consideration of gonorrhea infecting the region before or behind the compressor is due, like the vast majority of other advances in the study and treatment of genito-urinary diseases, to the great master, Felix Guyon.¹ This division into anterior and posterior urethritis is not only rational, but also the most convenient.

In most cases the symptoms of this disease vary according to the region affected; an effort will here be made, in studying them, to place them where they belong. But while attempting this, it will be found that there are symptoms which may show affection of either urethra. To recite these separately would encumber us with a new division. It seems better to adhere to Guyon's classification and, while using it, to mention wherever applicable the local differentiation, so important in treatment.

SYMPTOMS OF CHRONIC ANTERIOR GONORRHEA.

1. *Agglutination of the meatus.*—Some cases present, as the sole symptom of urethral disease, a mere cohesion of the meatus, most frequent on arising from sleep. This may take the shape of a slight, transparent pellicle or a crust formed by the dried discharge. When the discharge is so copious as to prevent its drying, it takes the shape of the morning drop, to be discussed farther on. It is important to ascertain, microscopically, whether the substance that even but agglutinates the meatus is the result of a diseased condition, or whether it indicates merely an increased normal secretion, due to erection during sleep. A particle of the "glue," pellicle or crust, rubbed with a drop of distilled water upon a cover-

glass, will prepare it for examination. But one such microscopic examination by no means suffices for diagnostic purposes. For some reason the specimen taken one day may contain only mucus or perhaps urethral epithelium; while the substance that causes the lips of the meatus to adhere but slightly may after several examinations be found to contain gonococci.

2. *The discharge*, like the agglutination, is often the only symptom which the patient observes. Its appearance and persistent reappearance, even without any accompanying inconveniences, harass him. It is difficult, without detailed study, to reach conclusions which will justify the physician in assuring the patient regarding the danger or innocuousness of this discharge.

3. *Description of the discharges.*—With a view to systematizing the description of urethral discharges, I beg to submit the following classification. While it is by no means exhaustive, I think it has the advantage of carrying a definition in each title: 1, thick bloody discharge; 2, thick green discharge; 3, thick yellow discharge; 4, thick white (creamy) discharge; 5, thick rice-water (grayish, opaline) discharge; 6, thick watery discharge.

The above discharges may vary or be mixed as regards consistence. Any of them may be thin, carrying thicker drops; they may also be mixed as regards color; thus, there may be a greenish-yellow discharge, or a yellowish-white one, etc.

When the discharge does not flow freely from the meatus, it may be present as, *a*, the morning drop (small, medium or large), varying from a dirty gray even brownish tint to the colorless appearance of raw egg-albumin; *b*, an excess of moisture, easily expressible from the meatus by stripping the urethra; *c*, an excess of moisture expressible to the meatus; *d*, an excess that can not be expressed, but remains within the meatus and is visible only on opening its lips.

4. *The abundance of the discharge* may vary in the same individual. In most cases of chronic urethritis, it presents only in the morning before the first urination (*goutte militaire*). In others it becomes evident an hour or two after urination. In others still, it appears only occasionally, as after fatigue, dissipation, the abuse of stimulants, etc.

5. *Color of the discharge.*—The morning drop especially may be creamy or yellow, or it may be grayish or opaline, or colorless.

6. *Consistence of the discharge.*—The discharge, drop, or mere excess of moisture in chronic gonorrhea may be as fluid as that of an acute specific urethritis; it may also be coherent, slimy and easily drawn out into long threads when taken between the fingers.

7. *Stains on garments.*—Very many patients see the sole evidence of disease in stains on their shirts. And indeed, when they or their physicians endeavor to strip from the urethra some more of the discharge

¹ Guyon: *Leçons Cliniques sur les Maladies des Voies Urinaires*.

that produces these stains, they succeed in bringing only a slight excess of transparent moisture to the meatus, but not expressible from it. Often these stains produce in the patient a greater disquietude than the discharge did, when it was evident. Such patients use all possible means to impress upon the physician the presence of the stains. It is nothing unusual to have a patient bring quite a laundry package for ocular demonstration. One of my cases wore his shirt a whole week, examined it almost hourly, and whenever he found a drop, encircled it with indelible pencil ring and marked it with the date and hour at which he discovered it. It is not rare to have a patient cut the stained portion from the shirt and attach it to labels, giving the above data.

8. *Relation between stains and discharge.*—When drops are discharged from the urethra, the stains on the garments bear a color-relation to the urethral discharge. As Diday has shown, a colorless drop gives the shirt a starch-like stain; an opaline drop gives the shirt a grayish stain; a white drop gives the shirt a yellow stain; a yellow drop gives the shirt a green stain.

9. *Urine stains* are sometimes confounded with the stains from urethral discharge. To recall their gross differences, I tabulate them as follows:

URINE STAINS.	STAINS FROM URETHRAL DISCHARGE.
Irregularly shaped; diffuse.	Circular or ovoid.
Large, with undefined edges.	Small, with sharply defined edges.
Color of same shade throughout.	Center darker than periphery.

10. *Diagnostic value of stains from urethral discharge.*—While excellent authors, *inter alia* Guiard,² do not attach very great importance to the stains from urethral discharge, these certainly merit attention. Thus the deeper in color and the greater in density a stain, the greater the likelihood of its containing gonococci; yet, a very light, starchy stain by no means excludes them.

11. *Microscopy of the stains on linen.*—When, for any reason, the patient can not be examined personally and it is necessary to prepare these stains for the microscope, it may be done by moistening the spot with distilled water, rubbing it upon a cover-glass and then drying, fixing, staining and mounting in the usual manner.

In many cases the discharge is so slight that it will not stain the linen. Then several hours must elapse before sufficient of the discharge accumulates to become at all evident in the meatus. Or it may be so small in quantity that stripping of the urethra is required to reveal its presence. In such cases the patient may not perceive it except after a night's rest, when it appears as the

12. *Morning drop (goutte militaire).*—This may show itself as a mere light drop of a pearly grey color, or through all the gradations to a very heavy, thick yellow drop. In some cases it does not take the form of a drop, but dries upon the lips of the meatus, slightly agglutinating them or, if the quantity be larger, may seal them with a thick crust. To obtain the drop for microscopic examination the patient must be examined before he has passed his first morning urine. When this can not be done, he must be provided with cover-glasses, and instructed in catching the drop.

13. *Absence of discharge* does not prove that the patient is cured. What is called "latent gonorrhea" (Guiard, *Annales*, 1884) may exist, especially in the posterior urethra, with no symptoms whatever, except as manifested by filaments, flakes or granules in the urine. I believe "residual gonorrhea" a more correct term for this condition. The "floaters" found in the first morning urine should be fished therefrom with a sterilized platinum loop and examined microscopically. If they can not be thus obtained, the urine may be centrifuged and the sediment examined.

14. *Absence of "floaters"* may not prove a cure either. *Ramonage* may then be advantageously employed with the other methods for determining the condition of the urethra, as described in another paper.³

15. *Itching or tickling* within the urethra, is one of the most annoying symptoms of chronic urethritis. It is especially aggravating when the symptom obtains in the posterior urethra. It is then often referred to the rectum. Such cases are subjected to all manner of treatment, even operations upon the anus and rectum, of course without relief. The reflex nervous symptoms resulting from this urethral itching or tickling, not infrequently drive the patient to desperation. In some cases the diseased area is so minute that its location is difficult even with the urethroscope. In extremely small infected spots, or perhaps a single one, it may not be found at all. Fortunately the vast majority of cases yield to dilatation and irrigations.⁴ In those few which persist, the urethra is prepared by this treatment, for more searching urethroscopy, until the diseased region can be brought to view.

16. *Painful urination* is not frequent in chronic gonorrhea, except when the patient has rendered the urine abnormally irritating by dissipation, or increased the local disturbance in the same manner by coitus or over-exertion. These may also reproduce the discharge or aggravate it, if present. Equally a meatus agglutinated, or sealed with a dried discharge, may render urination painful. The inflamed canal is distended to a painful degree, until the agglutination is torn away by the force of the stream. The tearing of the incrustation from the meatus carries with it superficial and sometimes deeper epithelium, producing at first pain alone and later ulceration of the meatus; until every attempt at urination is as exquisitely painful as it was in the beginning of acute gonorrhea. This can be avoided by teaching the patient to soak the meatus in a hot boric acid or very weak bichlorid solution, before urinating. The urine in chronic gonorrhea presents symptoms of import in both anterior and posterior infection of the organ and may be considered with the latter.

17. *The urethroscopic symptoms* of chronic anterior and posterior gonorrhea can not well be studied separately. And indeed they require, for their proper comprehension, an essay devoted to them. The only concise article on the subject that at present exists in English, as far as my knowledge goes, is the brilliant paper by H. R. Wossidlo.⁵

18. *The urethrometric findings* of chronic anterior gonorrhea merit investigation in a paper limited to the diagnosis of the disease.

² Valentine: "The Proofs of Cure in Gonorrhea," *Clinical Recorder*, April, 1898.

⁴ Valentine: "Chronic Gonorrhea; its Scientific Treatment," *Clinical Recorder*, January, 1898.

⁵ Wossidlo: "Practical Urethroscopy," *Medical Record*, September 7, 1895.

I have in the preceding endeavored to sketch the symptoms most frequent in chronic anterior gonorrhea. In doing so, I hope that the statement be not taken too strictly, as almost any of the symptoms can be simulated by disease of the posterior urethra.

There are also a number of symptoms which can not be separately studied; these will therefore be associated with consideration of

THE SYMPTOMS OF CHRONIC POSTERIOR GONORRHEA.

Posner⁶ hopefully says that acute posterior urethritis can heal without any special, and particularly without any local, therapeutics. This is fortunately true. Still, in view of the fact that 33 per cent. (Guyon and Jamin) to 85 or 92 per cent. (Ambert, Erand, Hassler, Jadassohn Letzel, Audry) of anterior gonorrheas traverse the compressor and infect the posterior urethra, it will not be well to envelop ourselves too firmly in what too often proves fancied security. Indeed it seems not remote that many of the sad results of residual gonorrhea are due to the fact of its lying unobserved in the posterior urethra, waiting, perhaps years, for the fitting occasion to become manifest. The comparative difficulty with which the posterior urethra ordinarily can be reached, may leave many cases unobserved until much later, when the most eccentric manifestations may suggest that it once was infected. Indeed, this infection in the acute stage may have been so insidious, as to be barely manifest, so that, to quote Guiard,⁷ it may have been chronic at the very outset (*chronique d'emblee*).

19. *Discharge*.—The discharge in chronic posterior gonorrhea is exceedingly variable. It may be so slight as to escape detection. Indeed there are cases in which the only gross evidence of infection of the posterior urethra is shown by shreds in the urine. If the patient's attention has not been attracted to them, their presence may be learned only when the physician examines the urine in quest of explanation for some other disease.

20. *Sudden large stain*.—Guyon and Jamin were the first to describe this symptom. It appears as a sudden large drop, with or without partial sensations of a slight ejaculation. Its stain upon the linen differs from the spots made by chronic anterior urethritis, in being much larger; when dried it usually has a whitish-yellow center, and becomes lighter colored and starchy toward the margins. Sometimes a stain of this character becomes evident to the patient only from its moisture. Not long since I had a patient who could, perhaps as a result of training, expel such a drop at will.

The presence of a large stain upon the linen may be accompanied by smaller drops, as described before. They would then evidence both chronic anterior and posterior gonorrhea, if on examination, the spots of both dimensions contain gonococci. There is no reason why another form of urethritis may not affect the anterior urethra, while the posterior is the seat of chronic gonorrhea, and *vice versa*. The explanation of the sudden large staining drop, as it escapes from the posterior urethra, is not very simple. The compressor being the anterior boundary of the posterior urethra, is a much stronger muscle than the sphincter vesicæ, which barely separates the urethra from the bladder. It is perhaps the presence of a heavier, thicker accumulation than the urine, in the posterior urethra, that stimulates the compressor to relax and

the accelerator to expel the substance. This must be coincident with too little urine in the bladder to overcome the sphincter. But the absence of this large drop, for the reason above given, is more frequent than its presence. The sphincter is more apt to yield than the compressor. Consequently when the accumulation in the posterior urethra is sufficient to be appreciable by it, the contraction of the region is more likely to throw it into the bladder. It then may be ejected with the first urine and convey the erroneous impression that a healing anterior urethra is the site of the disease. To obviate such misapprehension, the anterior urethra should be carefully washed before allowing the patient to urinate. The first urine, after the washing, will then carry the pathologic secretion of the posterior urethra, provided it be not too small and tenacious to be dragged along with the stream.

21. *Stains as evidence of spermatorrhea*.—A considerable number of patients, misled mainly by the publications of quacks, interpret the spots of chronic anterior or posterior gonorrhea as evidence of spermatorrhea, with all the horrors it is made to portend to them. In all cases, especially where the patient is threatened with sexual neurasthenia in consequence, it may be well to demonstrate microscopically the absence of spermatozoa from the harassing spots. Undeniably spermatorrhea may occasionally be coincident with chronic posterior urethritis and be provoked by it. But as the supposed spermatorrhea usually yields with the cessation of urethritis, or shortly thereafter, the patient may be safely reassured.

22. *A dry meatus*, as before indicated, may coexist with very copious pathologic secretion in the posterior urethra. Indeed, the entire anterior urethra may prove healthy, under urethroscopic examination, while large drops of discharge may be propelled from the posterior urethra, simulating a series of "petites ejaculations" as Guiard calls them.

23. *Supposed incontinence of urine*.—Some patients seek advice for inability to hold the urine, while they control it perfectly. They point to the stains on their shirts for confirmation of this diagnosis. It requires but little experience to distinguish the purulent circular stains from the diffuse stains of urine.

24. *Apparent defecation—or urination—spermatorrhea*.—A fairly large number of patients observe a thick, whitish drop either within or escaping from the meatus, during or after defecation, or at the end of urination. It is easy to understand how the final contractions of defecation or urination may force from the posterior urethra such secretion as was not carried off by the stream of urine. The microscope will decide whether the drop is due to chronic posterior urethritis, seminal vesiculitis, prostatorrhea or spermatorrhea.

25. *Apparent anterior urethritis*. Occasionally cases present simulating chronic anterior gonorrhea, by an almost continual discharge, containing gonococci. If the anterior urethra is carefully washed and then examined with the urethroscope, it will be found in perfect health. Holding the tube's distal extremity close to the sphincter, pus will be seen welling into it, sometimes in sufficient quantity, if the Oberlaender urethroscope is used, to extinguish the light. I saw a case where the manifestations were so characteristic of anterior urethritis that the practitioner who brought him feared to use intravesical irrigations lest he might thereby infect the posterior urethra.

⁶ Posner: Therapie der Harnkrankheiten, Berlin, 1895.

⁷ Guiard: Les Urethrites Chroniques, Paris, 1898.

Parenthetically I may say here, that this has never occurred. On urethroscoping the anterior urethra, it proved to be perfectly normal. The region of the compressor, however, bulged forward and slight pressure of the tube against it caused so large an extrusion of thick whitish discharge that it filled about one-third of the tube, suggesting a seminal emission. On examination this proved to be mainly pus, thoroughly loaded with gonococci. Under intravesical irrigations of potassic permanganate, this case soon recovered. The fact that such a chronic posterior gonorrhea can exist without infecting the anterior urethra, is doubtless attributable to a species of perhaps temporary immunity acquired by the gonorrhea, which was extended into the posterior urethra.

In view of the preceding, this manifestation of chronic posterior urethritis is not difficult of explanation. But when the discharge is very small in quantity and very tenacious, as in

26. *Chronic residual posterior gonorrhea*, without even the characteristic pain after urination, the only evidence thereof may be found in the shreds, filaments, flakes, etc., in the urine.

27. *Disturbances of ejaculation* are not infrequent accompaniments of very prolonged chronic posterior urethritis. Among these those most often found are

28. *Apparent aspermia*.—The patients so affected experience only a very slight or no sensation of the flow of semen through the urethra. On withdrawal for visual confirmation of the sensation, they find that nothing comes from the meatus. In such cases, the semen, instead of being vigorously ejected from the urethra, flows into the bladder and is carried off with the next urine. In several cases of this kind the patients confessed to a former habit of digital compression of the urethra, at the moment of venereal spasm, to avoid impregnation. One of these (a physician) claimed that he had acquired the power of compelling the semen to flow into the bladder, but after a gonorrhea had lost all ability to eject semen normally forward.

29. *Post-coital seminal dribbling*.—In some cases the semen is partially or entirely retained within the posterior urethra, and dribbles from the meatus upon cessation of the erection. This symptom is more frequent in urethritis ex libidine, than in chronic posterior urethritis.

30. *Painful ejaculations*.—In those not due to the ejaculatory spasm, drawing upon nerve terminals compressed in infiltrations of the anterior urethra, the pain may be due to irritation of the chronically inflamed posterior urethra, just as urine, the normal stimulant to vesical contraction, gives pain in cystitis, and as light, the normal visual stimulant, gives pain in iritis. These painful ejaculations, however, are by no means essentially of gonorrheal origin. In character, they may be lancinating, burning, extending from the meatus to the rectum, or radiating to the testicles and lasting some time after coitus, which may be followed by scalding on urination. They are most frequent in excesses, such as are likely to be committed by middle-aged men in sexual relations with very young women. The most aggravated case in which painful ejaculation was the exclusive symptom of chronic anterior and posterior gonorrhea, was that of an otherwise normal man, who screamed at the moment of ejaculation and fainted before entire conclusion of the act. Usually the patients with chronic anterior urethritis complain of no pain during ejaculation, or

only a slight burning. When the pain is sharp, lancinating, stabbing and extends to the region of the anus or rectum, chronic posterior urethritis is probably associated with disturbance of the anterior urethra and with or without involvement of the seminal vesicles or prostate, or both.

31. *Painful erections*.—These are comparatively rare when accompanied by sufficient genesic impulse to overshadow the pain. But there are cases in which erections without sexual desire are provoked by the presence of the chronic localized inflammation; they then stretch the tense areas or draw upon them, producing exquisite pain, while increasing the inflammation. Many a man has mere mechanical erections from an overfilled bladder. When the urethra harbors a chronic gonorrhea, the erections are, as a rule, more or less painful. They subside, however, as soon as the bladder is emptied.

32. *Excessive sexual desire*.—Another symptom, which, however, does not belong solely to chronic urethritis, but to affections of the prostate and vesicle as well, is what some patients call a "teasing" or "nagging" of the genesic apparatus. It urges a wish for coitus with partial erections, or only a slight swelling of the penis, or none at all. It is much akin to those localized troubles, as a long prepuce or tight meatus or other irritation which lead children to masturbation. These erections present mainly at night or on awakening. While the excessive sexual desire is evident principally during the day, it often disturbs sleep. In both conditions bromide of soda, bromide of potassium, or bromide of camphor in full doses will palliate the annoyance, but unless attention is paid to the patient's general condition, and unless his local affection is treated, they are of no avail.

33. *Premature ejaculations* frequently occur when chronic posterior urethritis has ceased to furnish other external manifestations. They may be so marked as to cause the patient to ejaculate, when his penis merely touches the external female genitalia. In extreme cases even accidental brushing against any part of a woman's garments, will cause an ejaculation, even without partial erection, or suggestion of sexual desire.

34. *Seminal emissions* are not infrequent in chronic posterior urethritis. In those cases due to abstinence from sexual intercourse they may occur once, twice, even thrice a week, and not be followed by any mental or physical disturbances. But if they recur several times in the same night, they are likely to become independent of sensual thoughts or dreams and then merit serious consideration.

35. *Urethral pains*, extending to the neighboring organs in some cases, even down the inner surface of the thighs, are not infrequently associated with chronic posterior gonorrhea. They generally occur independent of urination, but may be aggravated during ejaculation.

36. *Sexual neurasthenia* not infrequently supervenes in cases affected with chronic posterior gonorrhea. The seriousness of aggravated forms of what has grown into an essentially neuropathic condition merits separate study, such as has been given to it by Beard, who invented the term.

37. *The urine* yields symptoms of chronic gonorrhea, which might more properly be considered in a study of urinalysis. But the macroscopic findings are such that the patients soon learn them and attach importance to them beyond their real merit.

I propose here to merely outline those which are useful in common, rapid office-work. Ordinarily the patient is asked to urinate into two glasses, usually conical, not unlike sherry glasses. Guyon⁹ directs attention to the need of a preliminary thorough cleaning of the meatus, lest the urine contain the results of balanitis or the abundance and diversity of foreign bodies, that may be carried with it. He enumerates mineral dust, coal, wool, silk, linen, hemp, cotton, threads, bits of hair, feathers, grains of starch, etc. The first and second urine obtained as above, is in a measure inconvenient, and liable to yield false impressions. To overcome these I suggested, some three years ago, that large test-tubes be used in place of the conical glasses. They proved too fragile, however, for rapid office and dispensary work. I therefore substituted 12-inch ignition tubes. These give a column of urine equal in all parts, easy to handle, especially in those macroscopic examinations that are most frequently employed. Moreover, they are very convenient for transference to centrifugal glasses, to test tubes and to microscopic cover-glasses. Guyon⁹ devotes 365 pages to pathologic modifications of the urine; other authors have written volumes upon the subject. Hence, to attempt to more than glance at the most superficial macroscopic evidences of disease would be impossible in a paper like this. And in doing so, heed will be given only to those symptoms which attract the patient's attention.

38. *Malodorous urine.*—This is frequently the first symptom which patients observe. It sometimes has a fishy odor in chronic posterior urethritis and in tumors of the bladder, an excessively aromatic odor after taking balsams (e.g., santal oil); a violet-like odor—almost a perfume—after taking turpentine preparations, etc.

39. *Turbid urine.*—If the first urine is turbid it is generally accepted as evidence of anterior urethritis. This, however, is open to error, as mentioned in another portion of this paper, in connection with a consideration of posterior gonorrhea simulating anterior gonorrhea. If washing out the anterior urethra produces only clear wash-water and the first urine then passed is turbid, disease of the posterior urethra is fairly well established. If all the urine passed is turbid, it may be due to an inflammatory disease of any part of the urinary tract, except the anterior urethra, whose pus is generally washed away with the first 150 centigrams of urine.

40. *Dhomé's test.*—If the turbidity is caused by pus, the addition of a saturated solution of caustic potash and then twirling the tube, will soon provoke that ropy separation which Dhomé, who devised the test, called "snotty." This forcible term (rotzig) has, as far as I know, not yet found a more elegant and equally descriptive English substitute.

41. *If bacteruria* causes the turbidity, caustic potash will not separate the clear urine, as above described.

42. *Phosphaturia* can show the urine just as turbid as in either of the preceding conditions. A little nitric, hydrochloric or acetic acid will, especially after boiling the urine, clear it with the formation of bubbles, causing it to resemble champagne. This excess of phosphates may accompany the act of digestion, especially in dyspeptics; it may follow mental exertion, anger, fright or apprehension; it is almost always present in prostatic enlargement.

43. *Perfectly clear and brilliant urine* by no means proves absence of disease. Centrifuging the specimen may reveal slight but positive evidence that some part of the urinary apparatus is affected.

44. *Shreds, flakes, filaments, granules in the urine* are the symptoms which bring patients to us, long after other manifestations of disease have passed. Roughly these substances found in clear urine or in urine not so turbid as to conceal them, become smaller with the approach to restoration to health.¹⁰ With Guyon (*Maladies des Voies Urinaires*) and Guiard (*Les Uréthrites Chroniques*), I deem the following general classification of these substances carried in the urine the most convenient for general practical purposes:

PURULENT FILAMENTS.	MUCO-PURULENT FILAMENTS.	MUCOUS FILAMENTS.
Short. Multiple.	Very much longer. Less numerous, often have ends rolled into a ball, or are serpentine.	Uniformly transparent.
Opaque. Yellowish.	Not homogenous, but often consist of thicker spots, held together by a more transparent substance.	No opaque spots.
Fall rapidly to bottom; dissolve readily and increase turbidity.	Sink slowly and remain coherent a long time. By twirling the tube they can be made to rise from bottom.	Light; remain in the upper part or float on surface of the urine.
Easily removable from the urine with platinum loop.	More difficult to remove as proportion of pus diminishes.	Still more difficult to remove.
Easily spread upon cover-glass; no tendency to curl.	Tendency to roll into a thick slippery heap or serpentine mass upon cover-glass.	Tendency to roll into a clear, thick mass on cover-glass, where it dries very slowly and then is barely recognizable.
Microscopically: Large masses of leucocytes, few epithelial cells, no mucus.	Microscopically: Leucocytes, often with equal quantity of altered epithelial cells, englobed in a substratum of mucus.	Microscopically: Never exclusively mucus; always have some epithelial cells, often also a few leucocytes.

In the above comparative table, constructed for easy reference, I intentionally omit all mention of microbes. The coarsest shreds, which quickly drop to the bottom, may be free from gonococci, while the finest mucous filament may contain distinct groups.

In a general way, all that precedes applies to the urine in chronic anterior gonorrhea; but it is mentioned here because it is most convenient to examine both the first and second urines together. When manifestations point beyond doubt to chronic anterior gonorrhea alone, the first urine is usually considered without preliminary washing of the anterior urethra. But when doubt obtains, every effort should be made for proper differentiation.

45. *Washing the anterior urethra.*—Commonly, the patient having been instructed to come in the morning before he has urinated, the meatus is cleansed with cotton soaked in mercuric bichlorid 1:6000 and a sterilized, small soft catheter is introduced as far as the compressor. Hot boric acid 4 per cent. is injected through this catheter, until the solution that escapes along its sides is perfectly clear of even the finest granules. This washing with the catheter is perhaps the safest for those practitioners who have not much experience in the method which I find more convenient and efficacious. It consists in washing the anterior urethra without a catheter, as described elsewhere.¹¹ Naturally, in employing the irrigator, care must be taken that none of the wash-fluid

⁹ Maladies des Voies Urinaires, Tome I, p. 293. ⁹ Op. cit.

be injected into the posterior urethra, whose contents may be diluted thereby or have added to them the abnormal secretions of the anterior urethra. This vitiation of the test is more easily obviated by employing the irrigator I now use and recommend. The anterior urethra being thoroughly washed, the patient is instructed to pass his first 50 c.c. of urine into one tube and the remainder into another or others. If the first urine so passed is turbid, has coarse or fine shreds, filaments, flakes or granules, and if the subsequent urine is clear, the diagnosis of posterior urethritis, in the majority of cases, may be considered established.

46. *Turbid second urine.*—Even when the first urine passed after the cleansing of the anterior urethra is clear, the absence of posterior gonorrhea is by no means proven. The morbid secretion may be so slight and so adherent to the posterior urethra, as to render it not detachable by the urinary stream. The urethroscope is then the only means we have to determine the location of the disease.

Further consideration of these questions is relegated to a paper on the "Diagnosis of Chronic Gonorrhea," now in preparation. Even cursory attention to the preceding shows that nothing beyond an elementary study of the most salient symptoms of chronic gonorrhea has been contemplated. This may appear, at first, as an unwarrantable consumption of the time of this learned body. Yet, even among the best informed, symptoms are often hastily passed over as if familiarity with them had reduced their importance. My principal motive, I unhesitatingly confess, is to provoke a discussion which will doubtless be so instructive, as to fully repay me for the labor I devoted to this effort.

The large number of subjects touched upon makes it seem convenient to index them for rapid reference. The figures attached to the titles correspond to those in which they are mentioned.

CHRONIC PROSTATITIS AND ITS TREATMENT.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY H. R. WOSSIDLO, M.D.

BERLIN, GERMANY.

So many mooted questions still envelop chronic prostatitis that its presentation, especially in a necessarily brief paper, is attended with considerable difficulty. The symptoms, too, are so readily confounded with those of other ailments, save by most searching study, that oftentimes a patient with chronic prostatitis is treated for all manner of other diseases, unsuccessfully. To contribute what I can, in the time at my disposal, to the better comprehension of the disease is the task I have set myself in this paper.

The more or less severe tickling and burning in the urethra or at the glans, either incessantly or at intervals, the often increased frequency of micturition, the aching and stabbing pains in the anus, sacrum or perineum, the pain in the suprapubic region as well as the radiating pain along the lumbar region and the legs are well-known manifestations of chronic prostatitis. I hardly need mention the often present uneasy feeling or even painful sensation along the inguinal canal and in the testes, nor will it be necessary to describe the various nervous symptoms of neurasthenic origin in consequence of a chronic prostatitis.

However, it may be useful to emphasize the fact that the variety of symptoms arising from chronic inflammation of the prostate do not in every case point directly to the local affection, but on the contrary very often obscure the real nature of the disease, and may cause the original trouble to be overlooked. Another cause of this error is the similarity of the symptoms of chronic prostatitis to those of posterior urethritis. This, in a great measure, explains the wide differences that prevail regarding the frequency of chronic prostatitis. While, for instance, Erraud observed prostatitis in 70 per cent. of all cases of gonorrhea, and Posner as well as Finzer mentions the frequent occurrence of the disease, Fürbinger and others are of an opposite opinion. Lately, however, the attention of physicians has been drawn more closely to this question and observations of a larger number of cases are reported by Petersen, Neisser, Felecki, Fuller, Berkeley Hill, etc.

My own practice has convinced me that acute and chronic prostatitis could be diagnosed much more frequently if in every case of acute, subacute or chronic gonorrheal urethritis the patient's prostate were examined. Of course, I do not mean to say that in every case of acute or chronic gonorrhea the prostate must be affected. Considering the close connection of the prostate with the posterior urethra and also that the ducts of the prostate open into the same, it is easily understood how an inflammation of the posterior urethra can extend into the prostatic gland. But we meet with cases of prostatitis and seminal vesiculitis without any apparent inflammation of the

posterior urethra. It is supposed that in such cases an accidentally discovered chronic prostatitis has been chronic from the very beginning without having passed through an acute stage. It seems more likely that in such cases the infecting agents, the gonococci, did not rest long enough in the deep urethra to produce inflammation thereof, or that they did not find a suitable medium in the posterior urethra to grow upon, but wandered directly into the prostate.

The beginning of the acute prostatitis may be so mild, in such cases, as to cause no particular trouble to the patient, whose whole attention is directed to the more intense suffering from his acute anterior urethritis. Only after subsidence of the acute anterior do the symptoms of posterior trouble make themselves felt. Small wonder then that the physician overlooks the latter disease, unless he make it a rule to examine the prostate in every case.

Bacteriologically, also, the nature of the prostatic inflammation has been questioned. Finger in 1893 declared it indicated whether acute or chronic prostatitis is caused by an infection, by gonococci or a mixed bacteria. Neisser (German Dermatological Congress at Breslau, 1894) published several examinations he and Putzler had made, in which they found gonococci in the prostatic secretion. This has been confirmed by several other authors, and I can but endorse it. Although not always present, and although it is by no means easy to discover gonococci in the prostatic secretion, especially in chronic prostatitis, yet now and then we can detect some, as demonstrated several times in my post-graduate courses.

The text-books give as causes of chronic prostatitis: sexual excess, masturbation, gout, the internal use of balsams and traumatism. I do not deny the existence of chronic prostatitis after such accidents, but I believe that that they are very rare, and that the principal etiologic factor is gonorrhea. I am sure that in many fresh cases ascribed to one of the above mentioned causes, a still existing chronic urethritis could be detected if a urethroscopic examination had been made.

A symptom considered as being characteristic for chronic prostatitis is prostaticorrhea, that is an either constant or a periodical oozing of prostatic fluid from the urethra. We find this opinion in most of the text-books. In conformity with Feleki of Budapest¹, and with Groszlick of Warsaw², I found free prostaticorrhea, *i. e.* a continual flow of prostatic fluid very rarely in cases of chronic prostatitis. I believe that urethrorrhea—an innocuous mucoid secretion from the urethral glands—and spermatorrhea are in such cases mistaken for prostaticorrhea.

Defecation-prostaticorrhea and urination-prostaticorrhea, are terms employed to designate a flow of prostatic fluid following defecation or micturition. They are by no means as frequent as is generally supposed, still their existence can not be denied.

The general explanation for this symptom is in the pressure of hard feces against the prostatic gland and abdominal pressure in defecation or micturition. Another very probable view of its cause is given by Feleki. According to his opinion, the act of defecation and micturition, by providing an irritation to the inflamed and hypersensitive prostate, leads to the con-

traction of its muscular fibers, by which the prostatic fluid is expelled, as in coitus. It must, therefore, be borne in mind that chronic prostatitis may exist and often is present without prostaticorrhea.

Another symptom worth mentioning is not so generally known as being one of chronic prostatitis: it is the dribbling of urine after micturition. Several minutes after having urinated the patient feels drops of urine running from his urethra; this dribbling repeating after every micturition. Such patients have a sensation as if their bladder had not been entirely emptied; they shake the penis a long time after urination or try to squeeze the urine from the urethra by stripping the perineum to protect the clothes from the dribbling urine.

The same dribbling of urine (*harnnachträufeln*) is observed in cases of urethral stricture and hypertrophy of the prostate. We must consequently exclude stricture before we make a chronic prostatitis responsible for it. This symptom must not be confounded with incontinence or with ischuria paradoxa. In incontinence the urine dribbles involuntarily, the bladder never being filled, while ischuria paradoxa designates the overflow of the bladder in cases of stricture or prostatic hypertrophy. In our cases the dribbling of the urine seems to be caused by impaired function of the musculus compressor urethrae. According to Ultzmann, the compressor, being irritated by the inflammation, remains for a time in contraction, which prevents the entire emptying of the last drops of urine. These flow off as soon as the spasm subsides. Peyer, on the contrary, explains this "*nachträufeln*" by a weakness of the compressor muscle preventing the timely shutting off of the urethral lumen at the end of micturition.

I mention the great frequency of nervous troubles as a sequel of chronic prostatitis. The more or less constant uneasy or painful sensations along the genitourinary tract constantly draw the patient's thoughts to this region. Should he then, in addition to his disagreeable sensations, observe a degree of sexual weakness, incomplete erection or premature seminal emission, our patient's spirit becomes depressed. He is constantly worrying over his illness and loses all capacity for mental or physical work. In the worst cases general nervous debility sets in, not infrequently increasing to more or less complete exhaustion. Our patients become more or less obstinate hypochondriacs. It would be impossible to go into the details of all the nervous troubles complicating chronic prostatitis; they belong to the large group of neurasthenia sexualis. However, it must be understood that a great many patients suffer from such nervous disturbances without any affection of the prostate, and that others again with pronounced chronic prostatitis never show any nervous symptoms at all. The physician should make it a rule to examine every neurasthenic for chronic gonorrhea and chronic prostatitis.

We diagnose chronic prostatitis by examination of the prostate per rectum and by microscopic examination of the prostatic secretion. Rectal palpation of the prostate is done either in the recumbent position or by placing the patient with his abdomen over the head of a sofa or supported by pillows over the side of the bed with the shoulders depressed and the legs slightly apart. Care should be taken that the bladder is empty, otherwise an erroneous impression may easily be formed.

The patient being in the proper position, the index

¹ Feleki; Beiträge für Kenntniss und Therapie der Entzündung der Prostata und der Samenbläschen.—Cbl. für die Krankh. der Harn- u. Sexualorgane, 1895, p. 168.

² Monatsber. über die Gesammtleistungen auf dem Gebiete der Krankheiten der Harn- und Sexual-Apparates. Bd. ii. 3, 4, 5.

finger is gently introduced into the rectum and first glides softly over each prostatic lobe, determining its size and the character of its surface. Gradually a slight pressure on the prostate is made with the object of expressing some prostatic secretion for microscopic examination. The prostate will be found more or less irregularly enlarged. In some cases both lobes are irregularly enlarged and more or less painful to the touch; as a rule, however, one lobe is more affected than the other. The enlarged lobe may appear to be hard and of a more or less even surface, or of an irregular shape, presenting distinct nodules. This we find mostly in cases of follicular prostatitis, while an even, hard and smooth surface of an enlarged lobe is mostly due to a chronic interstitial inflammation; either one entire lobe may be soft and uneven, permitting the finger to be pressed deep into it, or we detect soft, easily impressible patches in both lobes, surrounded by somewhat harder tissue. The pain produced by the examination varies in intensity, some patients bearing a strong pressure comparatively easy, others complaining bitterly at the slightest touch.

A diagnosis of prostatitis can not be considered complete unless the prostatic secretion is examined microscopically. In cases without urethral or vesical complication we examine the prostatic secretion obtained by a gentle massage of the gland immediately after the patient has emptied his bladder. If in such cases, however, the quantity of the prostatic fluid is too small to appear at the meatus, it will mostly remain in the posterior urethra or flow backward into the bladder. In such a case we let the patient urinate into two glasses and ask him to keep some of his urine in the bladder. After massage of the prostate, the patient is ordered to empty the rest of his urine, which will contain the prostatic fluid.

It is much more difficult to obtain prostatic fluid *per se* in cases still complicated with urethritis or cystitis. It will then be necessary to exclude all substances coming from the mucosa of these organs. In complicating urethritis anterior we therefore wash the urethra with a catheter introduced to the bulb, with sterilized water or a boracic acid solution until the water or the solution contains no more pus or filaments, etc. We then order the patient to urinate and squeeze out the prostate after he has emptied his bladder. In case of a coexisting posterior urethritis or cystitis, we first carefully wash the posterior urethra or bladder after urination until our solution passes off quite clear. After having filled the bladder again with our solution we let the patient urinate it out, either partly or all of it. This is followed by a massage of the prostate.

The prostatic fluid so obtained very often shows macroscopic changes indicating an existing prostatitis. The discharge is very profuse, turbid, mucopurulent or purulent; in other cases, its macroscopic aspect differs very little from normal prostatic secretion. The decision as to the nature of the secretion is given by the microscope. According to the severity of the inflammation pus cells are found in varying quantities in the secretion. The discovery of pus cells in the prostatic secretion places the diagnosis of a chronic prostatitis beyond all doubt. Besides leucocytes we find the microscopic specimens to contain cylindrical cells in large quantities. Some cases of chronic prostatitis, present but few leucocytes in the secretion; these cells may be very abundant,

indicating a desquamative catarrh of the prostate. Red blood corpuscles are also occasionally found. According to Fürbringer, the spontaneous formation of seminal crystals in the secretion, without previous addition of phosphate of ammonia, is of diagnostic value for chronic prostatitis.

It has been mentioned above that gonococci may be found in the prostatic secretion; their discovery in the microscopic specimens demonstrating the gonorrheal origin of the disease. With regard to a differential diagnosis between chronic prostatitis and other genito-urinary diseases, we must exclude the following: 1. Urethrorrhea ex libidine. 2. Spermatorrhea. 3. Chronic posterior urethritis. 4. Other diseases of the prostate itself, especially prostatic tuberculosis. Urethrorrhea ex libidine produces a mucoid secretion from the urethra, which the patients may often take to be prostatic fluid or spermatic juice. Microscopic examination will readily show the harmless nature of this secretion and its origin; consisting mostly of mucous containing only a few pavement epithelium or cells. The abundance of spermatozoa in the secretion will easily permit the diagnosis of spermatorrhea. The difficulty of a differential diagnosis arises only when we find pus cells are mixed with the sperma. In such cases the pus may come from a seminal vesiculitis or from a diseased prostate. An examination of the semen will assist us. The latter usually appears in the urine in the form of gelatinous globules resembling sago and consisting exclusively of spermatozoa and epithelial cells from the seminal vesicles. In seminal vesiculitis these gelatinous corpuscles contain leucocytes. If leucocytes are found in the prostatic secretion alone and not mixed with semen, we diagnose prostatitis; but if, on the other hand, leucocytes are found in both secretions, we diagnose a seminal vesiculitis and leave the diagnosis of prostatitis *in dubio*.

In such doubtful cases rectal examination will often materially assist us. We find the diseased vesiculæ seminalis as elongated swellings beyond the prostate, smooth, round, fluctuating and painful to the touch or more or less hardened and nodular. I refer for particulars to Fuller's paper on "Seminal Vesiculitis," read before the New York Academy of Medicine, Section on Genito-Urinary Diseases, meeting of May 9, 1893.

The differentiation of chronic posterior urethritis and chronic prostatitis can easily be made by following the above-described plan for obtaining the prostatic secretion, after irrigation of the posterior urethra. Furthermore, urethroscopic examination will readily set aside all doubt. The differentiation between chronic prostatitis and tubercular prostatitis is of the greatest importance. It is not always easy to distinguish between a tuberculosis of the prostate in its beginning and a chronic prostatitis, especially as the prostatic secretion obtained by pressure on the prostate may in both cases contain leucocytes. Sometimes we may be able to discover tubercle bacilli in the secretion and all doubts are then dispersed. But the absence of the bacilli in a microscopic specimen does not exclude tuberculosis. We, then, must rely upon rectal palpation. In tuberculosis we generally find the prostate studded with tubercular nodules. Prostatic tuberculosis being very rarely primary, the diagnosis is easily cleared up by the detection of tuberculosis in other organs.

The prognosis of chronic prostatitis in the early

stages is not unfavorable: in the advanced form, especially when the prostate on rectal examination gives the impression of being flabby and distended with secretion, a cure is more or less doubtful. Yet even in these cases we can afford a great deal of relief to our patient. Many a neurasthenic can be cured of his complaints, although a residuum of his prostatic affection remains. Careful and proper treatment can do much, even if it has to overcome many difficulties, and even if it leads to only partial success. But in the latter case also, the general condition of the patient will be materially improved. The treatment of the disease must not only be local but also constitutional. It should never be forgotten that most of our patients are neuropathic individuals, and we must therefore from the beginning endeavor to gain their full confidence. If local treatment relieves them of their principal annoyances we must impress upon them the curability of their disease, with the object to distract their minds from the hypochondriacal thoughts regarding their local affection. This general treatment will be essentially assisted by corroborative measures. For anemic or lymphatic individuals we provide tonics, fresh air, mild exercise. Carefully directed hydro-pathic treatment will often benefit materially. Our local therapeutics should, first of all, be prophylactic, that means we should do our very best to prevent the setting up of a prostatitis in all cases of gonorrheal urethritis. A careful treatment of the latter will in many cases enable us to avoid prostatic complications. If, however, acute prostatitis sets in, we should try to cure it as quickly and as completely as possible. An early detection of acute prostatitis before the inflammation has involved the whole gland, is the first step to a quick cure. I repeat, therefore, the necessity of examining every case of gonorrhea on this score. As soon as an acute prostatitis is diagnosed, we should put our patient to bed and stop all urethral injections and endo-urethral treatment. I am in the habit of prescribing the following treatment for my patients with acute prostatitis: Twice a day, morning and night, a rectal injection of warm water of at least 35 degrees C., care being taken that the nozzle of the irrigator does not hurt when introduced into the rectum. At least one pint of warm water should be injected and retained as long as possible. Before making injection at night a hip bath should be given, as warm as can comfortably be borne. After the rectal injection has returned, which usually is followed by a mild stool, a suppository of one-third of a grain of iodoform to one grain, is inserted in the rectum. Should pain be severe, and should micturition be frequent and painful, I add half a grain to a grain of codeia phosphoricum to the suppository. Internally I give santal oil in capsules. By this simple treatment I generally succeed in relieving pain almost instantaneously. This is usually followed, in the course of one or two weeks, by a subsidence of acute prostatitis, the prostate generally becoming almost normal to the touch. Of course, abscesses of the prostate, when already formed, have to be opened. It is, however, very rare that suppuration leading to an abscess takes place if my plan of treatment is instituted at an early stage. When, after the acute stage is overcome, chronic enlargement with all symptoms of chronic prostatitis remains, massage of the prostate is recommended.

Cases of an established chronic prostatitis, especially very old cases, are much more difficult to treat. In

the great majority gentle massage of the prostate every second or third day will prove the most effective means of procuring, if not a complete cure, at least decided improvement. To hasten the reabsorption of the inflammatory exudations in the prostatic gland, I continue the warm rectal irrigations as prescribed for acute prostatitis, as well as the warm hip-bath and the iodoform suppositories. Lately I instituted another course of treatment besides massage of the prostate. An Arzberger rectal apparatus is introduced into the rectum and a stream of hot and cold water is conducted through it alternately. First a hot water stream runs three to five minutes through the double canula of the apparatus, and immediately after it a stream of cold water is passed through it. This is repeated until about 2 liters of each, hot and cold water, have made their circuit through the apparatus. By this alternate application of heat and cold in quick succession a rapid contraction and dilatation of the blood vessels of the prostate is produced, acting upon the gland almost like an electric current, only with less violence.

The first noticeable result of this treatment is that almost from very first application the patient experiences relief from the local pains, which in the course of a few weeks generally disappear entirely. All my patients are very fond of this kind of treatment, and I can strongly recommend it. I repeat that massage of the prostate is regularly done at the same time.

All the suppositories except those of iodoform, prescribed for chronic prostatitis, have yielded so little good in my practice that I have given them up entirely. Of course it is understood, that in treating chronic prostatitis, the patient should be cured of his chronic gonorrheal urethritis at the same time.

A NEW SIMPLEST PROCTOSCOPY.

Presented to the Section of Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association held at Denver, Colo., June 7-10, 1898.

BY THOS. CHAS. MARTIN, M.D.

LECTURER ON DISEASES OF THE RECTUM IN THE CLEVELAND COLLEGE OF PHYSICIANS AND SURGEONS, CLEVELAND, OHIO.

It has been complained that the best methods proposed for the inspection of the rectum require so expensive an armamentarium and such an infinite degree of painstaking practice on the part of him who would see, that the busy general practitioner can not hope to invade with his keen glance this darkest continent of special surgery. This is an error. On the contrary, as we shall see, no artificial means whatsoever are required for a complete ocular inspection of the rectum.

The elevation of the hips which sets in operation that principle of physics which governs the methods of Marion Sims' vaginal inspection (1845), Van Buren's rectal inspection (1871), and the method of the senior Allingham (1882), of Walter J. Otis (1887), and of Howard Kelly (1895), which controls my own procto-colonoscopy (1896), and which suggested Trendelenburg's posture, is, also, the chief feature of this the simplest proctoscopy.

The essentials of this method are a patient, an assistant and an operator having at least one finger on each hand. The patient is to be put into the knee-chest posture; the assistant is to put and to hold the patient; and the surgeon's fingers are to be used to open the anus, all in the following manner, to-wit:

1. The patient is to be completely anesthetized as

he lies on his back, and then turned toward the assistant and into Sims' posture.

2. The assistant is to station himself at the patient's knees. In his left hand he is to grasp the patient's feet. He is to lean himself against the patient's knees. He is to pass his right arm under the patient's hips. Now steadying the feet and bearing himself firmly against the patient's knees, with his right arm he is to lift the hips and pull the patient into the knee-chest posture.

Here, securely in the embrace of the assistant, the patient is to be balanced on his perpendicular right thigh. Exactly here, throughout the whole time of the surgeon's manipulations, steadily the patient must be held.

3. The surgeon is to close his hand and to point his index finger as shown in the accompanying illustration. (Plate 1.) So, likewise the other hand. The wrists are to be crossed, the hands placed back against

If this method be practiced, as I am persuaded it may be with facility by the general practitioner, I am convinced that the greater number of rectal diseases may be instantaneously diagnosticated. But I must declare that here, at diagnosis, the achievement of the simplest proctoscopy ends, for the reason that the operator's hands are so full of his patient he can do nothing at all for the disease which he may have discovered.

Under some conditions and amid some circumstances the rectum will not inflate. If there be a close stricture of the rectum, if there be malignant growth or other diseases of the rectum by means of which the gut's coats have become extensively filled and fixed with an organized plastic exudate, if for some reason the intra-abdominal pressure be abnormally increased, as it may be by the voluntary bearing down of the patient, as it may be by enormous intestinal flatus, or by ascites, or if there be an impinging

FIGURE 1.

back, and the nails of the index fingers placed one against the other, as shown in the accompanying illustration. (Plate 2.) The surgeon is to lubricate these fingers and gently insinuate them through the anus and place their ends beyond the borders of the levatores ani. This accomplished, the anus is to be divulsed in the direction of the ischial tuberosities, by the surgeon forcibly parting his fingers as is shown in the accompanying illustration. (Plate 1.) Under this manipulation the rectum becomes atmospherically inflated.

Now, provided the surgeon lower his head to the level of his fingers and then rise again, or stoop, or move a little from side to side, he may command under his eye a view of the atmospherically inflated rectum to the depth of six or eight inches (15.24 or 20.32 cm.) and in some instances he may behold even a part of the sigmoid flexure.

It is possible for the operator to manipulate his patient and to finish his inspection within two and a half or three minutes, provided the patient be in a state of complete anesthesia.

FIGURE 2.

uterus, extra-rectal growth or extensive infiltrating disease of the contiguous textures, rectal inflation by this method or by any other which is governed by the same principle is a physical impossibility; but this need not baffle the man bent on seeing by instrumental aids.

Practiced as described, when not embarrassed by the exceptions specified, this method will achieve its purpose and reveal to the surgeon that the transverse diameter of the rectum is variable; while in some places it is not more than an inch (3.54 cm.), in others it is more than four times this diameter.

The rectum may present to the eye of the imaginative observer the appearance of a chain of urinary bladders, communicating one with another by means of irregularly elliptical openings set at varying axes, and bounded by the non-parallel borders of the semilunar valves. In the normal rectum the air pressure smooths the mucous membrane evenly over the entire surface of the gut. The normal mucous membrane of the so-called ampulla appears at first wet and of a

shining bluish gray. As it dries, under the influence of gravitation the blue venous tint fades out of the gray and the wall becomes pink tinged. Presently it assumes the appearance of parchment, and sometimes it appears painted at rare intervals with ramifying little arteries which are crowded and overlapped by the larger companion veins; the latter are less arborescent and more suddenly dive and disappear in the bowel wall. In time, over all there comes a sheen as of collodion varnish and the vascular pictures fade save that one beneath the promontory of the sacrum. These phenomena appear exactly as described only in the healthy rectum; in the diseased organ the color varies much.

Should the operator deviate from the prescribed directions for the manipulation of his fingers and so twist his hands as to divulge the anus in the antero-posterior direction instead of laterally he invites defeat upon himself; for in the male the fixation of the perineum and the immobility of the coccyx interfere with the requisite dilatation; while in the female, the extreme mobility of the perineum and particularly the backward displaceability of the coccyx will allow such traction to be made upon the levatores ani as to pull their inner borders parallel and almost together, and in consequence the wider the female's anus be opened antero-posteriorly the closer it shuts laterally to rob us of our view.

1077 Prospect Street.

PRIMARY CARCINOMA OF THE AXILLA.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY D. W. GRAHAM, M.D.

CHICAGO, ILL.

Carcinoma of the axilla consecutive to a primary focus of the disease in the mammary gland, or some other organ or structure, is a matter of almost daily occurrence in the experience of the surgeon. But primary carcinoma of the axillary region is rare enough to be worthy of discussion, especially as it raises some important questions in the fields of histologic anatomy and pathology, and of practice. There is no apparent reason why this region might not be the site of the squamous celled, or true skin carcinoma, as frequently as any other in the body. Primary cancer of the axillary skin is, however, exceedingly rare. Of 7297 primary cases of carcinoma analyzed by Williams 571 were of the skin, but of these latter only three were axillary.

There is no doubt but that occasionally a primary carcinoma of the breast will first manifest itself clinically through the infection and enlargement of the axillary lymphatics. The primary nodule, small, slowly-growing and deeply seated, and the conditions present for quick invasion and rapid progress of the lymphatic infection would give a pathologically secondary, but a clinically primary tumor in the axilla. While this is the explanation usually given and generally accepted for most carcinomatous tumors first appearing in this region it is applicable only to a small number of such cases, and should not apply except when the axillary tumor shows an exclusively lymphatic histologic basis.

There are two structures found in the axillary space in which carcinoma is prone to originate, which will account for nearly all cases of true primary carcinoma

in this region. One of these is the supernumerary mammary gland tissue more or less perfect or rudimentary, found occasionally, and the other structure constitutes the large convoluted, tubular sweat glands, which are constantly present.

The most complete recent exposition of the subject of supernumerary mammary glands in the human subject is that by W. R. Williams in the *Journal of Anatomy and Physiology*, Vol. xxv, 1891. It is shown that there may be one, two, or three of these above the normal gland on a line diverging outward to the axilla—two on the border of the pectoral muscle, and one in the base of the axilla. The latter is the least frequent. Most frequently these supernumeraries are rudimentary masses lying wholly beneath the skin and neither visible nor palpable, resembling in gross appearance ordinary subcutaneous connective tissue, but microscopically they show some of the normal elements of the gland. These subcutaneous "mammary lumps," as they have been called, may be wholly detached from each other and from the normal mammary gland, or they may be joined to the latter by an isthmus of the same kind of rudimentary tissue. In 132 consecutive cases of carcinoma in the mammary region in females Williams found that 13 of them had their origin in supernumerary structures quite outside the normal glands. None of these, however, were located in the axilla proper.

The sweat glands of the human axilla have been specially described by such anatomists as Sappey, Koelliker and others, but it remained for C. H. Creighton to demonstrate their peculiarities and emphasize their significance from a pathologic standpoint. In the Royal Medico-Chirurgical Society transactions of 1882, Vol. lxx, page 53, he reports three cases of axillary carcinoma in dogs, originating in the large axillary sweat glands. Spencer Wells, in Wood's Monographs, Vol. iii, No. 1, 1889, reports a case of axillary carcinoma with the microscopic findings which seem to demonstrate that it originated in the large, tubular sweat glands in the manner described by Creighton. They are regarded as a kind of rudimentary organ of cutaneous secretion in the human when compared with similar structures in the lower animals, and, as Wells observes, are subject to all the risks of such survivals or rudiments. These glands, while also found in the groin and in the areola of the breast as well, are looked upon as midway in structure, with their large acini and amount of secreting surface, between the ordinary sweat glands and the mammary gland. They have their distinguishing histologic features by which they can be identified with ease. They are situated under the skin and not in the skin like other sweat glands and their ducts open into the hair follicles. They are large enough to be detected as firm, round bodies in the subcutaneous tissues in a dissection. It is quite probable that a more careful study of specimens of primary axillary tumors would show these glandular structures to be the point of departure for the morbid process in the majority of cases, rather than the supposed axillary supernumerary mass of mammary tissue. A study of the clinical histories also of those cases which have been put on record is suggestive in this same direction.

The two following cases have served as a basis for this brief paper on this subject:

Case 1.—Miss DeC., aged 50 years, came into my hospital service in June, 1898. The right axilla was filled with a hard mass which was already causing edema of the arm by pressure.

The history and physical characteristics all pointed to carcinoma. Nothing abnormal could be detected in the breast nor in the tissues intervening between this and the tumor. Removal of the growth required an unusually difficult dissection, a section of the axillary vein being extirpated with the mass. Six months later the patient returned with a nodule not larger than the end of a finger, just beneath the skin, about the middle of the upper hemisphere of the mammary gland. The skin was involved and adherent to the nodule. The breast was amputated by my colleague and a microscopic examination was made by Dr. William E. Schroeder, who had already examined the tumor removed six months before from the axilla. Both specimens were demonstrated to be carcinoma.

Case 2.—Mrs. A. C., 30 years of age; had had acute mastitis with suppuration while nursing a child in 1895. The examination, December, 1897, revealed a hard tumor in the base of the right axilla as large as a hen's egg, and which had been developing for a number of months. There were several small nodules, which had developed later, extending along the border of the pectoral muscle toward the breast. The latter was equally consistent throughout and except that it was firmer and slightly larger than the left breast, it seemed to be perfectly normal. The main tumor was movable, and to all appearances did not involve the overlying integument. The several smaller nodules seemed to be enlarged lymphatic glands.

The operation consisted in removing both the tumor and the breast, together with the isthmus of intervening infected tissue. Dr. L. Hektoen made a careful microscopic examination of the specimens and reported there was no carcinoma of the breast proper, it being, however, in a state of chronic inflammation. The ducts were much enlarged and dilated, filled with semi-solid secretion, cheesy like and surrounded throughout the whole breast and nipple by hyaline connective tissue. The main tumor from the axilla was simple carcinoma with considerable fibrous tissue, and the intervening lymphatics were some of them carcinomatous, and the opinion was expressed that the nodule nearest the mammary gland was an outlying accessory portion of the gland, although before the operation there seemed to be a clear intervening space between them.

It is to be regretted that in neither of these cases did it seem possible to demonstrate by the microscopic examination the exact anatomic structure or characteristics of the tissue in which the carcinoma appeared.

After a thorough search of medical literature I have been unable to find but eighteen reported cases of primary carcinoma of the axilla which can be accepted as such. I have rejected a number of those that have been so reported, because the evidence shows that they were either sarcoma or secondary carcinoma. Even two or three of these eighteen, which follow, might prove to be sarcoma if fuller histories were obtainable or if the specimens had been microscopically examined since the time when there began to be histologic differentiation between sarcoma and carcinoma.

Case 1.—H. Snow, London *Lancet*, March 12, 1898, p. 717. Female, aged 47. Hard mass, filled whole axilla. One and a half years' duration. Skin adherent. Breast healthy, but removed with tumor because the disease seemed to be traveling toward the mammary gland, the normal direction of infection being cut off.

Case 2.—C. E. N. Kelly, London *Lancet*, March 26, 1898, p. 859. Female aged 80. Tumor size of pigeon's egg in middle of axilla at fourth rib. Hard and fixed to the chest wall. Skin ulcerated. No apparent connection with breast. No operation. Its course was watched and it extended gradually along the border of the pectoral muscle to the breast, which became involved. No lymphatic glandular enlargement. The opinion is expressed that the tumor did not originate in an outlying free nodule of mammary gland tissue.

Case 3.—F. P. Paul, Transactions Pathological Society, London, 1895, Vol. xli, p. 153. Female aged 29. Tumor appeared in axilla while nursing child, then disappeared, and reappeared when nursing next child and took on all the characteristics of typical scirrhus. Tumor excised. No connection with the mammary gland. Cut section exuded white secretion, like inspissated milk. Thinks it originated in sweat glands, but this opinion is controverted by Williams, who believed it arose from a detached axillary mammary lobule. (*British Medical Journal*, 1894, Vol. ii, p. 1405.)

Case 4.—H. Walton, *Medical Press and Circular*, London, 1895, Vol. ii, p. 45. Primary hard cancer in axilla. Operation.

Several recurrences. Subsequent operation. Immunity of the breast from cancer.

Case 5.—Spencer Wells, *Wood's Med. and Sur. Monographs*, 1889, Vol. iii, p. 18. "Cancer and Cancerous Diseases." A case of axillary tumor removed. Female aged 46. Microscopic examination showed origin in the sweat glands. Breast free from disease.

Case 6.—Bailly, *Le Progrès Médical*, Second Series, 1887, Vol. v, p. 53. Female aged 68. Tumor of right axilla. Three years' duration. No connection with mammary gland. Microscope showed hard carcinoma.

Case 7.—Pied, *Bulletin Société Méd. de la Tours*, 1886, Vol. xxvii, p. 62. Carcinomatous tumor of the axilla. Extirpation.

Case 8.—J. Congoureaux, *Gaz. Med. Chi.*, Toulouse, 1881, Vol. xiii, p. 137. Voluminous carcinoma developed spontaneously in the right axilla without morbid change of the breast.

Case 9.—J. Coates, *Glasgow Med. Jour.*, 1879, Vol. xi, p. 322. Melanotic cancer removed from the axilla by MacLeod.

Case 10.—Von Mosetig-Moorhof, *Ber. d. K. K. Kranken*, Wieden, 1898, p. 190.

Case 11.—R. A. Cleemann, Transactions Pathological Society, Philadelphia, 1867, p. 151. Female aged 70. "Lump" in axilla $1\frac{1}{2}$ inches in diameter of four years duration. Excised. A year later another lump appeared between the cicatrix and the breast. Both tumors pronounced epithelioma, the latter described as composed of a half dozen hard, rounded bodies in size from a split pea to a marble, making a single mass. The appearance of the mass and the skinned to the suggestion that the origin was in the appendages of the skin—"the sweat glands."

Case 12.—C. F. Maunders, Transactions Pathological Society, London, 1862, Vol. xii, p. 229. Male aged 30. Open cancerous ulcer involving the axillary artery, not excised. Began as a lump in the axilla one year before, every clinical feature of carcinoma, but not demonstrated microscopically.

Case 13.—R. Alba, *Espana Med.*, Madrid, 1862, Vol. vii, p. 388. Axillary cancer. Extirpation by Prof. Natalie Cano. Reported cured.

Case 14.—S. Benavides, *Chron. d' I Hosp.*, Madrid, 1856, Vol. iv, p. 206. Occult cancer and scirrhus tumor in the right axilla. Extirpation.

Case 15.—H. Ohm, *Deutsche Klinik*, 1854, Vol. vi, p. 288. Female aged 40. Tumor arose from birthmark in axilla which had been accidentally abraded and ulcerated a year previously. Other tumors developed in the axilla which proved to be of the lymphatics. The tumor was removed and it appears that the breast was not affected.

Case 16.—M. Marjolin, *Bulletin de la Société Chirurgie*, Paris, 1862, Vol. iii, p. 410. Female aged 57. Left axilla; small painless tumor several months duration. This was extirpated and consisted of three distinct nodules. The microscopic examination was made by M. Robin. He remarks that the tumors are of a very rare species. His report, together with the clinical evidence and gross appearances given is almost conclusive that the case was one of primary carcinoma of the large sweat glands if interpreted in the light of today.

Case 17.—R. W. Smith, *Dublin Medical Journal*, 1838, Vol. xii, p. 65. Female aged 30. A hard, movable, painless tumor appeared in right axilla. Afterward the axillary vessels and surrounding tissues became involved. One year and some months later a tumor was noticed in the breast. No operation. Autopsy showed carcinoma of the stomach and other viscera. The author reports the case as one of primary carcinoma of the axillary glands.

Case 18.—M. Marrotte, *Jour. de Méd. et Chirurgie*, Vol. iv, p. 107, 1831. Male aged 22. Tumor filled right axilla. Extirpated and examined microscopically. Report says several forms of cancer and cysts full of blackish fluid were found. It is questionable whether this was not a case of sarcoma.

In a given case of carcinoma, originating in and apparently confined to the axilla, established surgical principles imperatively require wide removal of integument, fat and lymphatic tissue from the axilla and of the latter two structures along the border of the pectoral muscles to the breast, whether apparently invaded by the disease or not, and in most cases some of the muscular tissue, as well. But it becomes a very important practical question whether the breast itself should or should not be included in the operation. It would be the safer course to remove the breast in all cases, but some exception can be made to this general rule consistent with good surgery, the question hinge-

ing on the age of the patient, the extent of the disease, and the length of time it has existed.

CONCLUSIONS.

1. Primary carcinoma of the axilla is probably more frequent than the small number of recorded cases would seem to indicate.

2. When present it originates, *a*, in the large tubular convoluted sweat glands peculiar to this region, *b*, in supernumerary mammary gland tissue more or less rudimentary, or *c*, in the true skin; and as to relative frequency in the order named.

3. When the disease appears first in the axilla and later in the mammary gland the most satisfactory and the most logical explanation is that there has been retrograde infection through the lymphatics from the axilla to the breast.

4. When the lymph glands and channels or other tissues between the axillary tumor and the mammary gland are at all infected, or suspected, the gland should be removed along with the tumor and the intervening infected tissues.

5. In any case in which the breast is not removed it should be carefully examined at short intervals for the first manifestations of disease.

DISCUSSION.

Dr. CHARLES A. POWERS of Denver—The practical importance of this subject can not be overestimated, and it shows that in addition to the removal of the primary neoplasms of the breast, those of the axilla should be subjected to the same management. The rule is absolutely established that no part of the mammary gland is to be allowed to remain without a most thorough and careful examination. It is well known by all surgeons and is becoming more and more appreciated by physicians and the laity. Our success lies in early recognition and extirpation. During the past year I have removed from the anterior axilla a nodule the size of a hen's egg. Clinically, differential diagnosis could not be made between a benign and a malignant growth, and the pathologist who examined this specimen called it a supernumerary mammary gland, which was the seat of the fibro-adenoma, although it might just as well have been malignant.

Dr. OCHSNER of Chicago—At the inner limits of the axilla, and the lower edge of the pectoralis major muscle, there is a point at which I have seen three carcinomatous growths, and in each one the nodule was first movable underneath the skin, consequently it could not have originated from the sweat glands in the skin, nor from anything except glandular tissue. The only glandular tissue there would be a portion of the mammary gland, and cancer in this region can originate precisely as could epitheliomatous growths elsewhere. In this particular location, if the points in its development are observed, it is perfectly plain that the cancer must come from a supernumerary mammary gland. I have frequently found extensions of the mammary gland a considerable distance from the gland proper, and I cannot see why there should not be extension in the axillary direction as well as in any other. Under these circumstances, the carcinoma would originate precisely the same as from any other lobule, only the lobule is slightly displaced.

Dr. A. D. BEVAN of Chicago—There are two possibilities that must be borne in mind, one of which is the occurrence of a small primary focus of carcinoma, which is overshadowed by the secondary growth. It may be that the primary growth is a very small nodule in the mammary gland, while the secondary mass may be in the axilla. In one of Dr. Hirschfelder's cases, there were extensive deposits of carcinomatous tissue in the prostate without any primary lesion. I recently had a case in which I amputated the entire outer end of the scapula and clavicle for supposed sarcoma, but postmortem examination showed it to be a case of carcinoma. In these cases we must imagine one of two possibilities; first, that there was a small primary focus overshadowed by the secondary mass, or second, the encapsulation of a piece of epiblastic tissue which has developed into carcinoma.

Dr. J. B. MURPHY of Chicago, Ill.—In the cases observed by the author, I would like to ask if the tumor was situated deep primarily or superficial primarily, that is to say, was the skin movable over it in the early stages? Dr. Ochsner laid great stress on this point. We all know that we can find car-

cinomatous growths in the sweat glands which may or may not have originated in the mammary glands, and every surgeon has noticed that suppurative foci may be found in connection with the skin. Upon opening these tumors they will be found to contain a caseous material, and are largely made up of invaginated portions of the epiblast. These cysts are very common and frequently do not appear to be attached to the skin.

Dr. WILLIAM L. RODMAN of Louisville I would like to report a case similar to Dr. Graham's, which occurred in a male about 60 years of age, living in Jeffersonville, Ky., who was by occupation a ship carpenter. The case was unquestionably one of scirrhus carcinoma of the axilla, which was removed, and as it was the first of the kind I had ever seen I followed it up until death. This case bears out the remarks of several of the speakers, and I am sure you will occasionally find primary carcinoma in the axilla, although most of these cases are doubtless sarcoma. Dr. Bevan makes a good point when he states that a very small lump in the breast may be overlooked and the growth in the axilla considered as primary when it is really secondary. All of us have seen cases of this kind, and I have had my attention drawn to it by patients. As to the treatment of these cases, I can add nothing to what has been said by the essayist, but would like to insist even more strongly on one point, and that is the danger of infection of the lesser pectoral, which should be removed. It seems to me that it is even more necessary in these cases to remove the glands than it would be the primary growth in the breast itself.

Dr. GRAHAM, in closing—Referring to the microscopic findings in Dr. Powers' case, it is stated that many cases of fibro-adenoma, so-called, originate in these sweat glands, as well as in the axilla and the mammary gland, and it is probable that most fibro-adenoma originate in these glands. Dr. Bevan's statement is exactly opposite to what I claim, and there is no reason to my mind why a focus in the prostate should not be secondary as well as primary. It is true we may have a primary focus in the axilla. I believe you will admit that we do have tissue in the axilla capable of giving rise to primary carcinoma, and one of my cases proves this. With regard to Dr. Murphy's questions, the integument in the second case I reported was movable over the tumor, while in the other case the mass was very large, and the skin was tense. It must be remembered that these sweat glands are under the skin and not in it. No doubt we can have a supernumerary mammary nodule in the male as well as in the female.

POST-OPERATIVE INSANITY.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY R. HARVEY REED, M.D.

SUPERINTENDENT AND SURGEON-IN-CHARGE WYOMING GENERAL HOSPITAL;
PRESIDENT WYOMING STATE MEDICAL SOCIETY.
ROCK SPRINGS, WYOMING.

For want of a better term I have adopted this one to indicate certain mental aberrations following operations. That very slight operations are not infrequently followed by severe attacks of insanity is beyond a question; at the same time the most severe operations on those who are insane are frequently followed by the return of their normal mental faculties.

Why this unfortunate complication should follow certain operations in both male and female is a question which up to the present time has not been fully settled from a pathologic standpoint. Statistics on this important subject are severely wanting, and it is believed on the part of the writer, that notwithstanding a few cases of post-operative insanity have been reported from time to time in the journals, a great many more have not been reported, possibly for the want of knowledge as to their cause, or maybe a hesitancy on the part of the operator to announce to the world that he has operated a certain case which has been followed by some form of insanity. The fact that we do have these cases occurring and that their causes are illy understood is certainly a sufficient excuse for having selected this subject, the study of which we hope will throw more light upon this important clinical question.

Among the few cases which have been recorded, the following is the synopsis of a case operated by Dr. Sprague, published in the American Medico-Surgical Bulletin of May 2, 1896, in which he reports having operated a very nervous and hysterical case, which in childhood had been a subject of chorea. At the time of the operation the patient had reached the age of twenty-four, and had given birth to two children, having sustained a laceration of the cervix and perineum at the time of the first birth, but outside of this misfortune her health was practically normal. Without going into the details of the case, she was operated eight months after the second birth. On the eleventh day after the operation she was taken with mania, her temperature at that time being 101 and continued to rise until it reached 106, when she died. The writer states that during her entire illness she partook of a large amount of nourishment consisting of milk and eggs; that her urine was examined with negative results; that the patient never had a chill or chilly sensation, and that the only pus found was one drop about a very superficial suture; that she never had the appearance of a patient suffering from sepsis, the lips and skin being normal in color almost up to the time of her death. In closing his article he stated "now, was this a case of acute mania and meningitis due to her sensitive and nervous condition, or should we throw out entirely the nervous condition as a cause of her trouble and ascribe it to the results of sepsis? If the latter, was there sufficient pus to produce such violent results?"

In considering the main features of this case it is difficult to understand why this particular patient should have had an acute attack of mania with so small a quantity of pus, when other cases with large quantities of pus and often suffering from septicemia, do recover without any mental aberration.

In referring to the records of the Protestant Hospital I find that my colleague, Dr. J. F. Baldwin, operated a patient Sept. 19, 1895, removing a hematomata of the right broad ligament in a lady, age 28, with good habits, normal urine, bowels regular, appetite good. On the third day after the operation her temperature rose to 103; on the fourth day it dropped to 99 $\frac{3}{4}$, at which time she became delirious, but happily responded to the use of bromids and finally recovered from the operation Oct. 9, 1895. The doctor informs me that he has had several cases of post-operative insanity but fortunately none of them had resulted fatally, and that in no case was he able to determine any particular cause for the mental aberration.

Through the courtesy of Dr. J. Collins Warren and Dr. G. W. Nickerson, the author was very kindly furnished with a report of the following case of "delirium nervosum." A German woman about 65 years of age, was operated Sept. 23, 1895, by Drs. Warren, Nickerson and Stone for cancer of the sigmoid flexure, producing intestinal obstruction. The operation consisted in making an artificial anus. The hospital reports show that on recovering from the anesthesia she seemed dull and drowsy, which was followed by restlessness and delirium continuing two days after the operation, when she became noisy, talking continually, but sleeping on an average of about eight hours a day. She partook plentifully of nourishment. Four days after the operation her mental condition changed from that of excitement to that of muttering delirium. The sutures were removed on the fifth day but the delirium continued. On the sixth day after

the operation she became very nervous and had hallucinations which consisted in seeing and hearing parties around her. On the thirty-second day she refused nourishment, on the thirty-ninth day she became hysterical and for a time was restless and sleepless. On the forty-fifth day she assumed a melancholy mood, subsequently she became violent, but at other times almost rational.

These extremes of mental aberration continued with little or no rise of temperature until she died, April 1, 1896, 190 days after the operation. This case is interesting from its prolongation and the variety of hallucinations manifested. When we realize the large number of cases that die from cancer without any hallucinations or mental aberration of any kind and on the other hand the large number of patients who suffer from fecal fistulas or an artificial anus, who likewise are free from any form of insanity, the question naturally arises, why should this particular case develop such marked conditions and what are the peculiarities that give rise to them?

The writer has had occasion to meet with several of these seemingly pathologic freaks, among which he might mention the following: Mrs. S. M. C., age 56, white, two children, the youngest about twenty-six years of age, was an unusually strong healthy woman, and with the exception of a laceration of the cervix and perineum was in normal health. Her family history was good, but owing to the long continued laceration of the perineum she became afflicted with prolapsus of the uterus. She was admitted to the Protestant Hospital of Columbus, Ohio, June 24, 1895, and operated June 26, 1895, the operation consisting in freshening the edges of the uterus and suturing them in place and the usual operation for lacerated perineum. The patient made an eventful recovery and was about ready to return home when she was seized with a violent attack of mania, which became so severe as to necessitate her removal to the Columbus State Hospital for the Insane. Her mental condition was so bad when taken there that Dr. Richardson, the superintendent, despaired of her recovery, and for weeks looked upon her case as an exceedingly grave one, although there was no physical evidence associated with the operation that would indicate any cause for her mental aberration. In the course of about three months she began to improve, and one day it dawned upon her that she had been insane, and she fully appreciated her surroundings, and remembered distinctly the hallucinations which had afflicted her during the three months previous, which consisted in imagining she was incarcerated in some jail in which she daily expected to be massacred. Notwithstanding all the delusions, she has fully recovered, and today is in the enjoyment of her normal health and attending to her household duties. As there was no pus infection in this case and no family history leading to insanity, it still remains a conundrum in my mind as to why such a severe attack of mania should have occurred after so trivial an operation, which was devoid of any complications.

I recall another case which was operated at the Protestant Hospital, May 21, 1895, in which I removed the uterus and ovaries. The patient made an uneventful recovery, but after returning home became melancholy, and for a time it seemed that it would be necessary to remove her to the insane-asylum, as her melancholy changed to mania of a vicious charac-

ter. The latter only lasted a few days, and in the course of a few weeks, I am reliably informed, her mental condition became normal, and at the present time she is in the enjoyment of good health. In studying the history of this case I find that fifteen years prior to her operation she had a very severe attack of uterine hemorrhage which was suddenly checked and was followed by an acute attack of insanity, making it necessary for her to be taken to the insane-asylum for treatment, where she remained some nine weeks, when she was dismissed in a convalescent condition. During all this time she had suppression of the menses; three weeks after her return home the menstrual period was regularly established and her normal health returned, and no symptoms of mental derangement manifested themselves until after the operation above referred to.

I will now report a case which is the reverse of those I have just mentioned. Mrs. N., aged 37, of German descent, was admitted to the Protestant Hospital, Nov. 15, 1896, suffering from dementia of twelve years standing, dating from the birth of her last child. At this time she sustained a laceration of the cervix, followed with fibroid degeneration of the uterus. During a part of this time she was cared for in the Columbus Hospital for the Insane, and in 1892 had convulsions in connection with her dementia. Three years prior to the operation, she received a fracture of the arm and immediately became a raving maniac. Her case being a chronic one, Dr. Richardson, the superintendent, advised operative interference, and on Nov. 18, 1896, I operated, removing both ovaries and the uterus. The latter I found very much degenerated, while the tubes were atrophied and the ovaries had undergone cystic degeneration. For a week the patient improved rapidly, her mental condition becoming very much better, the urine being passed through its normal channel, but at the expiration of this time a seepage of urine was discovered in the vagina, which aroused my suspicions lest I had by some mistake injured the ureter. By more careful examination I found that by catheterizing the right ureter the urine obtained was normal, but in catheterizing the left ureter through the fistulous opening, the urine was loaded not only with pus but with albumin, leading me to the conclusion that there was degeneration of the left kidney and ureter. Consequently on Dec. 13, 1896, I made a nephrectomy of the left kidney, which I found enlarged and located abnormally high. In order that no mistake might be made, assisted by my colleague, Dr. Means, I passed the urethral catheter through the fistulous opening into the ureter and allowed it to remain there until I made an exploratory incision into the abdominal cavity, which developed the existence of a diseased left kidney, which was then removed by the lumbar operation, and was found to contain numerous cysts, many of which contained pus. My patient made a rapid and uninterrupted recovery from this second major operation, and for a time the urine passed through its normal channel, but to my chagrin and surprise some three or four days after the operation I found the urine again seeping through the vagina, and on further examination discovered a calculus, which had evidently formed in the right ureter, producing necrosis and suppuration, and was finally broken up and removed through the vagina, thus leaving a fistulous opening. Excepting this my patient still continued to recover, but I found that the

continued irritation of the urine worried her, causing a return of the mental aberration.

I again called counsel, consisting of Drs. Baldwin, Means and Dunham, and it was decided that an effort would be made to implant the remaining ureter into the bladder. The patient was prepared accordingly, and assisted by Drs. Means and Baldwin, another abdominal section was made which not only developed the fact that the right kidney was abnormally small and located unusually high, and that the ureter was very large, with a fistulous opening at its lower end communicating with the vagina, but instead of the ureter passing over the psoas muscle and iliac artery immediately underneath the peritoneum, it passed under them, thus making operative interference doubly difficult. Notwithstanding this the ureter was dissected out, when I found that it lacked an inch and a half of being long enough to be inserted in the fundus of the bladder. I then proceeded to dissect the bladder loose from its moorings, but after having done that, the ureter was still too short, and I next proceeded to dissect the kidney loose and bring it down until I was enabled to implant it into the fundus of the bladder, after which the kidney was anchored, the bladder sutured as firmly as possible to the abdominal parietes, the toilet carefully looked after to avoid sepsis, and the patient returned to her room to await results.

Strange to say, notwithstanding that the patient was a debilitated, insane woman, she made a rapid recovery both physically and mentally, but in spite of all our care there was some leakage of the urine both through the abdominal and vaginal wound, which in the course of a few weeks ceased, and I am pleased to state that the patient is now reported doing her own housework, her mental condition normal and her physical condition very much improved.

Owing to the fact that the cases thus far referred to were all females, it might be misleading in the study of this very important and mysterious subject. In order that your minds may be disabused in this respect, I beg leave to briefly report one or two cases which occurred in the male.

J. D. S., age 35, referred to me by Dr. Hyde of Nelsonville, Ohio, suffering from a stellate fracture of the patella, in which the latter had been broken into five fragments. An operation was made at the Protestant Hospital in which the fragments were sutured together with heavy silk-worm gut and the knee joint thoroughly cleansed of blood-clots and fragments of bone. The patient made an uninterrupted recovery until the ninth day, when he was suddenly taken with an acute attack of mania, jumped out of bed and started through the ward, and it was only through the combined efforts of the nurses that they were enabled to get him into bed. From that time on he was deranged and it was only by putting on special apparatus that we were enabled to keep him in bed. At the time of his attack of insanity the wound looked perfectly healthy, but immediately following that it became inflamed and swollen; the exercise in walking through the ward and the efforts in getting him back into bed had evidently torn some of the fragments of the patella apart, which was followed by acute suppurative synovitis, septic infection, and in spite of free drainage and antiseptic treatment, resulted in death.

This case was one of a strong, healthy man whose family history was good, and up to the ninth day

after the operation no evidence whatever of mental aberration was observed, neither was there any physical condition indicating septic infection; hence the sudden attack of insanity which continued for several weeks before final dissolution closed the scene, is unaccounted for.

Mr. L., age about 50, referred to me by Dr. Kelly of Galion, Ohio, was suffering from tubercular osteomyelitis, necessitating an operation and the removal of a sequestra which extended nearly two-thirds of the length of the tibia. The ordinary operation was performed, the wound cleansed with bichlorid solution and packed with iodoform gauze. The patient did well for four weeks when he suffered from a sudden attack of insanity, which at first was of an intermittent character, but gradually became worse until he became a raving maniac, necessitating an apparatus to keep him in bed. During all this time, which covered a period of some two months, his wound continued to repair by granulation until complete recovery ensued so far as the operation was concerned, but his mental condition, although not so bad when he left the hospital, continued deranged and remained so after his removal home, and up to the last account the writer obtained regarding his condition.

It is needless to say that I was more or less chagrined when I was brought face to face from time to time with these cases of so-called "delirium nervosum," lest it were some fault of mine in operating or dressing the case, or some neglect on the part of those who cared for it in the hospital, but my mind was greatly relieved when I found that such a distinguished surgeon as Dr. John B. Hamilton, editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, was meeting with similar conditions, in which he informed me he had called in the best experts on mental and nervous diseases in the city of Chicago, who up to that time had failed to discover any particular cause for these mental disturbances. In order that I might have further information in regard to this very serious complication, I took the liberty of writing to several distinguished surgeons throughout the United States, making inquiry as to their experience in cases of this class. Among numerous answers which I received was one from Dr. John B. Deaver, of Philadelphia, in which he says, under date of March 28, 1896:

"The cases of post-operative insanity which have occurred in my practice have all presented a clear history, *i. e.*, perfectly sane all their lives up to time of operation. The patients who have been so affected have not had any febrile disturbance and the cause could not have been attributed to drugs. I have not had any deaths occur, yet I know that this sometimes happens."

On the other hand, Dr. Howard A. Kelly of Baltimore, in a letter received under date of March 17, 1896, said: "I will very gladly look up the matter and write you in a day or so," but up to date he has failed to report the results of his investigation, leaving us to speculate as to whether he ever had a case of this kind, or if he had, as to whether he was willing to report it.

Dr. John A. Wyeth of New York wrote me under date of March 15, 1896, in which he said: "In regard to your subject of post-operative insanity, I do not think I could contribute anything of interest. I do not now recall a single case of well-marked insanity resulting after an operation."

Dr. R. Stansbury Sutton of Alleghany, Pa., writes me under date of March 15, 1896, in which he says: "I have never seen a woman who was sane when operated, become insane afterwards. I have frequently operated insane women. Some of these have been cured by the operation and three have not been cured. I suspect that in some instances the excessive use of iodoform, at and after the operation, is conducive to, or rather productive of, insanity."

Under date of March 13, 1896, Dr. Rufus B. Hall of Cincinnati wrote me: "I have had five patients develop acute mania after sections and one after vaginal hysterectomy, the mania lasting from twelve to thirty days in four cases and three or four days in one case. The patients all recovered and are now well. Two of these patients had been insane before operation. One suffered several months but had been well a couple of years; the other had been in the asylum for a year at one time and two and a half years at another time. She was out of the asylum a year or more when she developed an ovarian tumor, for which the operation was made. The three others never had any mental trouble preceding the operation."

I will not take time to quote further from correspondence, which seems to be as varied as the cases that have fallen under my own observation. Certainly the cause ascribed by Dr. Sutton can not be attributed to any of the cases I have reported, except the one with the osteo-myelitis, for that was the only one in which I used iodoform, and yet I had a series of cases ranging over a period of years, no two of which were alike, and on the other hand, as has been stated by Dr. Sutton, I operated a case of chronic insanity which was submitted to several capital operations, which not only recovered from the operation but from the insanity.

My paper is already too long to enter into a discussion of the pathology of these anomalies, and if it were not, the clinical evidence obtained up to the present is so confusing that I doubt whether we could arrive at a satisfactory conclusion. I am aware that septicemia may produce a species of ptomaines followed by mental aberration, but the preponderance of evidence of the clinical cases which I have reported does not show the presence of septicemia, and hence I am compelled to eliminate this as the predominating cause, for in many cases the mental disturbance did not begin until after the patient had recovered, or only lasted a short time in cases where there was no evidence whatever of the existence of septicemia or pyemia.

Whether climatic influence has anything to do with it or not I am unable to say, but one thing I do know, that since I have been connected with the Wyoming General Hospital, which is located nearly a mile and a half above sea-level, in the heart of the Rocky Mountains, I have not seen a single case of post-operative insanity, notwithstanding we have had many severe accidents, saying nothing of the operations for lacerated cervix and other gynecological operations, while in Ohio a number of similar operations were followed by post-operative insanity, with and without the existence of pus.

I hope that my contemporaries will be free to report these very interesting and troublesome cases and that from these reports we may, in the near future, be able to determine their pathology and, if possible, avoid their occurrence.

QUESTIONS IN THE TREATMENT OF CON- GENITAL DISLOCATIONS OF THE HIP.

Presented to the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY HARRY M. SHERMAN, A.M., M.D.
SAN FRANCISCO, CAL.

In the treatment of congenital dislocation of the hip by modern methods, reduction of the dislocation by manipulative or operative means, we must wait long for a success to become an assured one; we may not have to wait long for failure. Therefore any one reporting success can do so, at the present time, only with the qualification that the case is "successful up to date." Tomorrow, or the day after, may witness a relaxation, and the work will have to be finally counted a failure or will have to be done over.

I have practiced the operative and manipulative reduction only during the past two years, and my experience will let me speak of but the beginning of my cases which I would count successes; of my failures I can speak with more definiteness. I do not intend to detail methods or case histories *in extenso*. The literature of the operation is becoming very voluminous, and the main facts have been many times repeated. I shall suggest only a few points which specially interest me by reason of their difficulty, or because I do not fully understand them.

OPERATIVE REPOSITION.

I have done the reposition by operation nine times, and the first time I could not definitely locate the acetabulum, and in my endeavors there was considerable injury done to muscles and other tissues. The matter is, after all, simple enough if one bears in mind the point which has, I think, been properly made; that the femoral head is always within the capsule, and that the latter always has its original attachments to pelvis and femur. Therefore, if the femoral head be found (and this is an easy matter) and the capsule covering it be incised, the finger, slipped into this incision, will pass at once along the elongated capsule to the acetabulum. There is more importance in this early finding of the acetabulum than at first sight appears. The incision through the skin and fascia has done no injury to a part having an active function; the muscular covering of the head can be traversed by simply separating the fibers with a blunt instrument; the only other tissues that need cutting are the capsule and the floor of the acetabulum, the former to permit access to the latter and the latter for the hollowing out of a proper socket. Knowledge of this simple and obvious path to the joint may save a tedious time of search and much mutilation of muscles, and the preservation of the function of the latter is of definite practical importance. In addition to this, the shortening of the time of the operation directly lessens the danger of sepsis; and suppuration in one of these cases is, I chance to know, a very tiresome thing.

In one of my earlier cases I noted that when the plaster of Paris splint was first removed the joint was apparently freely movable, but in a limited range; later there was a rigid limitation of motion, the limb being held flexed and adducted; and still later, though there was no massage nor passive movements practiced, the rigid flexion and adduction ceased, and full extension and ample abduction became possible. I had compared the *mechanical* conditions in these

reduced congenital luxations to the conditions that pertain in an ordinary healed hip joint tuberculosis; in each there was some alteration in the shape of acetabulum which made it a less suitable socket for the femoral head; in each there was some irregularity of the femoral head which made it a less perfectly adapted mechanical part; and in each there was some shortening and distortion of the femoral neck which made it a shorter and less efficient lever for the action of the thigh abductors. Therefore it seemed quite natural that, in my little case, the limb should take the position of the third stage of hip joint tuberculosis; and later, it seemed plausible to argue that the increased range of motion was due to late absorption of the plastic effusions which had occurred immediately after the operation, just as we see a practically stiff tuberculous joint regain the great part of its function with the subsidence of the tuberculous process. Other cases have not followed the course of this one, and three hips, in two children, have gone on to practical ankylosis, the amount of motion permitted being too little to be of any use; and in each instance the stiffening has come on gradually, and while the child was using the limb with apparent perfect comfort. This is difficult for me to understand, unless it is due to cicatricial contraction. When the splint is first removed the cicatricial tissues in the joint are young, and there is then free motion through limited arcs; this motion is enough to be quite easily measured by the goniometer. Later, there has been gradual lessening of motion to practical joint rigidity; and this has come on during the period when the cicatricial tissues have been aging and contracting. Furthermore, the location of this cicatricial tissue must be inside the articulation, not in the tissues of the capsule nor in the muscles around the joint. I believe that for this reason: I operated early this year, for the reduction of an old irreducible traumatic dislocation of the hip in a child 4 years old. The operation was on the lines of a Lorenz operation for a congenital dislocation. I found that, at the time of this dislocation, the capsule had been torn entirely from the femoral neck, and I discovered it lying collapsed in the acetabulum, and quite firmly adherent there. To effect the reduction of the head it was necessary to cut all of the internal rotator group of muscles. Now, it was not practical to suture the capsule to the femur, so it was pulled into its place, as nearly as possible, and left; nor could all of the cut muscle be sutured, but only a part of it. Therefore, in this case, I had made more extensive sections of tissues than I have found necessary in congenital cases, and there was a very questionable arrangement of the capsule; and yet, after an uneventful healing, I had a joint with a very satisfactory range of motion in a useful arc, and a most gratifying functional result. But in this case the articular cartilage on the femoral head and in the acetabulum was quite normal, while in the congenital cases, the femoral head is put into a cavity hollowed out in the bone of the pelvis. It is true that this cavity has a floor that is made in part of cartilage, for in all these cases ossification is incomplete and the unossified triangular piece of cartilage between the three segments of the os innominatum is in the center of the floor; but this is not articular cartilage, rather cartilage that must eventually become bone, and all around it the cancellous tissue of the bone is exposed, and from this granulation tissue may grow, may become adherent to the femoral head

and neck and bind it closely, and more closely, in one position.

I have been obliged to come to this theoretic conclusion because I have been unable to find the records of a postmortem on one of these cases, made late enough after the operation to display exactly the final anatomic result in detail. Now, if this is so, the question of securing a freely movable joint, even in a limited range, is a most difficult one: for any forcible motion will only be a fresh trauma which will require more cicatricial tissue for its repair, and anything short of a motion that will make the head move freely within its socket, will be only the stretching of tissue today, which will contract tomorrow, to be stretched again the day after. This last is the method of Lorenz, and it is tedious, painful and it is reported to get but partially satisfactory results. I have not practiced it myself for the reason I have already given, that I thought the late absorption of plastic effusions, under the stimulus of the active motions of the child, would slowly free the joint; but the three stiff joints that I have, out of my little series, have shown me that this tiresome after-treatment of the operative cases may be necessary.

In my last case, a girl of 11 years, in whom the operation is not two and one-half months old, and whose hip was becoming progressively stiffer, I have, under an anesthetic, broken up adhesions and made sure of free motion. During this manipulation there was no tendency to relaxation and the head moved freely in the socket, with but a little crepitation at one place. From this operation I feel quite sure that it was the fastening of the head to the acetabular floor that limited motion, and that my task is to establish here a nearthrosis by the persistence of sufficient motion to prevent reattachment: to favor the development of a bursal sac and a pseudo-cartilaginous lining of the acetabulum similar to that in a true pseudo-arthritis sequent to a fracture of a long bone. A second manipulation, under anesthesia, a week after the first, found the joint, which had been treated by passive motion and massage in the interval, free to move from full extension through 90 degrees of flexion, and through 20 to 25 degrees of abduction from the usual position, and this with less joint crepitation than formerly. If this can be maintained a most satisfactory result will have been achieved. In all of the manipulation of this joint with its restricted motion, it is interesting to note that it never once has resembled the restricted motion of hip-joint tuberculosis. The two conditions, similar in the point of limitation of motion, have been otherwise markedly contra-distinguished.

In another case there has been relaxation of both hips. Just when this occurred I can not say. The child left the hospital in apparently good and satisfactory condition, and when I next saw her, a year later, the dislocation had recurred. I suppose that, in this case, I had neglected the advice Lorenz gave me, to make big acetabula; but as I am to be permitted to repeat the operation this coming fall I will not theorize, but will wait to find out the cause at that time.

In the last case of this series to be mentioned, but one of my comparatively early cases, I was quite unable to bring the femoral head down to the level of the acetabulum, and so I made an entirely new socket, the lower portion of which overlapped the upper portion of the real socket. This was done in a relatively thin part of the bone and opened through the ilium

into the pelvis, and into this hole the head was thrust. This case supplicated and was tedious. Under the patient and painstaking dressings and redressings of my associate in the case, Dr. C. M. Armistead, the child finally recovered, but with an ankylosis. The limb, however, is in a good position and is a thoroughly satisfactory means of support and progression.

MANIPULATIVE REPOSITION.

In this procedure the chief obstacle is in the disposition of the capsule at the acetabulum; for extending upward from the acetabular rim to the head in its luxated position, it lies directly over the hollow of the acetabulum and closes it except for a small and narrow slit at the upper part—a slit that is often so narrow that it will not, until it has been enlarged, permit the passage of the head. The manipulation endeavors to tear this slit larger, but this definite object can not always be definitely accomplished, and the head may be placed in the acetabulum, but with a double layer of the voluminous capsule interposed, the head having failed to pass through the slit and having pushed the folded capsule before it. If this occurs the disaster of relaxation is inevitable.

There were ten hips in eight children on which manipulative reposition was attempted, the first having been done about nine months ago, and in nine hips the fact of reposition was apparently accomplished. In one child, a girl 7 years old, who had bilateral dislocation, one hip was irreducible, the other was reducible, but its location in the acetabulum was so very insecure, probably because of the folded interposed capsule, that the idea of keeping it there was abandoned and the child reserved for operative reposition. This has not yet been done. In another case, a boy of 6 years, the reposition seemed to be accomplished, but the evidence was not satisfactory, and so an incision was made, the finger carried down to the capsule and the parts explored by direct palpation. Quite a large hematoma was found just outside the capsule, and it was demonstrated that the femoral head was really in the acetabulum. This was a simple incision with a finger thrust in it, but it supplicated, bacteriologic examination showed the streptococcus and the child is yet under treatment. The reposition has, however, been maintained and there is a little "shake motion" in the joint, but ankylosis must be the inevitable result. Another case, comparatively easily replaced, became relaxed within six weeks, again probably because of interposed capsule, and in spite of being continually in apparatus—a plaster-of-Paris spica—and in bed. A second reposition seems, up to date, more successful, and the child has now begun to walk in her spica. Another went her whole six months of splint restraint and a month of freedom from splints, and then relaxation occurred. After a little interval of rest the reposition was repeated and splint restraint begun afresh. The final result is now many months off. In a small boy the reposition was accomplished and maintained for six months before the splint was entirely left off. When the splint was definitely removed the whole limb became swollen and congested and flexed at the hip and knee. The child was merely kept in bed and the condition gradually abated, but a certain amount of rigid flexion at the hip persisted, and motion was very much limited. Under anesthesia the joint was shown to be free of ankylosis and reposition was maintained, but the

long head of the rectus femoris and the neighboring fascia lata was very tense when joint extension was made. A subcutaneous section of these was done and a plaster-of-Paris spica put on, and this is still in place. In another little boy the present conditions seem to promise complete success and I have been much tempted to take off my splint—a little spica which does not reach below the knee—before my appointed time. In this little splint the child runs and jumps and climbs, with a hardly appreciable catch in his step, and with perfect freedom and comfort. He must, however, live out his predetermined time of splint restraint, and that will last another month. At the time of changing the splints the facts of maintenance of reposition and freedom of joint motion have been established.

I did not expect that the difficulty I had experienced in the operative cases with stiff joints, was to follow one in the manipulative reductions; but one joint, reduction having been done six months ago, comes out of splint treatment with the reduction stable, but the joint quite rigid in a position of slight flexion, slight abduction, and slight out rotation, and his gait is consequently very awkward. This is the only one that has, at any time, presented such very definite rigidity after manipulative reduction, and the causation is a little obscure. It is not unknown that exudations of lymph may take place in sprained joints, undergo organization and cripple joint motion. (Moulin on Sprains, 42. et seq., Klemm, *St. Peter. Med. Woch.* 1897, No. 28, quoted by A. J. M. S. p. 224, 1898.) I found quite a hematoma just outside of one joint which I had replaced by manipulation, and then cut down on to verify my result. It may be that the stiffness of this particular joint is due to some such cause, and it is being properly massed and subjected to passive movements with the result that it is gradually becoming more movable. It is to be noted, however, that the shallow acetabulum throws the femoral head somewhat forward; and the outward rotators of the hip are adapted to the luxated position, and the reposition puts them on the stretch; and both of these conditions—in this case, at any rate—tend to cause an outward rotation of the limb.

Finally, one little girl with a bilateral dislocation was subjected to manipulative reposition with apparent success, but this proved to be of but temporary duration. A second attempt to reduce proved a failure on one side, and, while the head could be put into the socket on the other side, it could not be made to stay there. I decided to repeat the operation I had done for the traumatic dislocation; and so I cut down on the left hip and found that in the original manipulative reposition the head had been put into the acetabulum but the double layer of capsule had intervened. Section of this flap with a tenotome disclosed a very poor acetabulum, but one that could be used, and so the head was thrust in it, and the capsule overlapped at the point of section and the pelvic portion stitched to the femoral neck. On the other side the incision of the capsule gave vent to 6-8 c.c. of dark synovia, as if a synovitis had been set up by the previous manipulations. The acetabular pocket was more open but the slit needed to be enlarged for satisfactory reposition. In this instance the slit cut in the capsule was sutured, the stitches being inserted some way back from the margin, so as to draw considerable of the capsule into a thick fold, and so strengthen it and lessen its extent. In both cases

gauze drains were used and superficial sutures of silk-worm gut. By this means I know I have the femoral head properly in the acetabulum; I know there has been no injury to the acetabular articular cartilage, and no special invitation for granulation tissue to develop, and to cause ankylosis; and I know that the disposition of the capsule is such that the upward thrust of the femur in supporting the body, must drive the femoral head deeper into, rather than out of the acetabulum. These points are gained by neither the operative nor the manipulative reductions of Lorenz and Hoffa. What may be the final result I can not say, but it ought to be a good one, and to favor that, and lessen all unnecessary adhesions and stiffness, early manipulations and passive movements are to be begun; as soon as the superficial wounds are healed I shall turn the child over to a masseuse.

This recital of difficulties must not be taken as counting against the operation. The reports, as they have come to us from Europe, have recited brilliant successes, and I have related my incomplete cases and my failures to indicate the difficulties that must be overcome, and the disappointments that may meet us. Still, with the exception of one case where there is practical ankylosis of both hips, and the cases where relaxation occurred, each case treated has been markedly benefited, even though an ideal result has not been reached. As these children grow the new articulation should become firmer, and the limb more useful for support and progression, and this is in direct contrast to the unreduced cases, in which increasing body weight causes stretching of ligaments and muscles and lessens, progressively, joint stability. I have lately examined three women with unreduced dislocations, and their lives are being distinctly narrowed by the increasing difficulties in getting about. It is right that we should try to save the children of today from being overtaken by that fate.

DISCUSSION.

Dr. JAMES E. MOORE of Minneapolis—Although this is a deformity that we are not likely to meet with every day, it is present all over, and I personally know of at least twenty-five cases. Experience has taught us that mechanical treatment is unsatisfactory, and very few cases have been reported where mechanical treatment has yielded satisfactory results, so that we are compelled to look for other methods. Among the best are the operations of Lorenz and Hoffer; the former the bloodless, and the latter the bloody. I have had but little experience with the bloodless operation, but on one occasion started in to do the bloodless and wound up by doing the bloody. I had a very sad experience in this case, and the patient recovered with an ankylosed joint, so I would not advise trying to combine the two operations. The technique is very simple, although the Lorenz operation is more complicated than the present one. Dr. Bradford advises that you begin your incision just below the anterior superior spinous process of the ilium, and cut downward and outward, making a longitudinal incision through the fascia lata. The anterior margin of the tensor vagina femoris comes into view, and you cut right down upon the capsule at once. You then make an incision into the capsule and cut around until you can turn the head of the bone out, separating it absolutely. Failing to follow the proper point will cause much difficulty in finding the acetabulum. It is only by having such men as Dr. Sherman give us their results that we can begin to formulate our ideas.

Dr. SHERMAN, in closing—As to the substitution of the bloody for the bloodless operation, the injury that is done to the tissues in endeavoring to reduce the dislocation without incision is very great. I have found hematoma in one case at the end of a week, and in every case, ecchymosis results. If the laceration of the soft parts can be avoided, the bloodless operation will give a more satisfactory result. It is necessary to regard ankylosis of the limb in a good position as preferable to permanency of the dislocation, and the usefulness of the limb is so much greater that it is worth while, as unreduced dislocations become progressively worse.

THE TIME TO OPERATE IN APPENDICITIS.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1897.

BY H. D. NILES, M.D.

GYNECOLOGIST TO THE HOLY CROSS HOSPITAL,
SALT LAKE CITY, UTAH.

For a long time the appendix and adjacent parts were distinguished as being the only structures in the human body where the known presence of pus was not an indication for its removal. Ignorant of the etiology and pathology of the inflammatory diseases of this region, restrained by exaggerated ideas of the hazards of intra-peritoneal surgery, few surgeons had the courage to oppose this violation of a generally recognized law; and for many years, under various names, appendicitis received only those treatments that were purely medicinal, symptomatic and palliative, while the results depended alone upon the unaided reparative efforts of nature.

But since the pathologist has conclusively proven that from the very nature of the disease, neither internal medications nor external applications *can* have any direct effect upon this disease, and that all clinical evidence to the contrary must of necessity be deceptive, and since modern methods and perfected skill have so nearly annihilated the dangers of intra-peritoneal surgery, the surgical conception of appendicitis, based upon the teachings of pathology, has gradually supplanted the old empiric treatment, which never has had any support, except unconfirmed clinical testimony.

In taking this all-important step toward the proper management of an infected appendix, some have hesitated and wavered and are still reluctant to rely entirely upon the principles of modern surgery to guide them in their treatment, for they maintain that there *are* times and there *are* cases where an infected appendix should be left within the body. Others regard this as a purely surgical disease, to be treated *always* in accordance with those surgical laws that hold good on other parts of the body. Hence, a consideration of the time to operate in appendicitis always includes a discussion of the following question: *Are experienced operators ever justified in recommending that an infected appendix be permitted to remain within the abdomen longer than is needed to make the necessary preparation for its removal?*

Arrayed on either side of this question are earnest, sincere men of the widest experience, whose opinions and judgment we all value and respect. So long as this uncertainty and marked difference of opinion exists in the treatment of this very frequent, acute and grave disease, we can not hope to command or merit the full confidence and trust of the laity nor to be quite free at all times from doubts and misgivings ourselves, as to our choice of plans. Until we are approximately in accord upon the main points of treatment, appendicitis will continue to be a proper subject for thoughtful consideration and reconsideration, alone and in discussion.

In this paper I shall express as clearly and as briefly as I can the line of reasoning and thought that has led me to believe that *the known presence of an infected appendix within the abdomen is always an indication for its removal.*

Appendicitis has its origin in an infection effectually imprisoned within the appendix, out of the possible reach of external or internal medication or natural

drainage, cut off from the cecum by inflammatory occlusion of the canal and separated from the nearest external outlet by the parietal peritoneum, several layers of muscles and fascia and the skin. This infection may be mild and limited, free from danger and causing but little distress; or it may be most acute and virulent, producing local and general changes most dangerous to life and health. We are, as yet, unacquainted with any signs or symptoms that enable us to distinguish positively one grade or stage of inflammation from another. This infection is in a useless organ that is easily and safely removable ordinarily, but which lies in dangerous proximity to tissues which are certain to be involved if the infection spreads. This extension of the infection we are absolutely powerless to arrest except by surgical removal of its source. Treated medicinally or left to nature, 10 per cent. of all cases end fatally in the primary attacks and more than 25 per cent. die ultimately. The causes of death are systemic infection, peritonitis or obstruction of the bowels, hence the surgeon's aim is to prevent, arrest or limit septic absorption and local and diffuse infection of the peritoneum. Local infection may occur either by direct extension of the inflammation or by sudden rupture of the distended or softened appendix, permitting the escape of its septic contents. Diffuse peritonitis may be produced by the same causes, or by leakage from an appendiceal abscess. A very large proportion of those who do not die suffer from recurrent or chronic appendicitis, or from the more or less remote effects of bowel or omental adhesions which occur to some extent in nearly every case.

These, I believe, will be accepted as fair statements outlining the conditions which confront us in every case of appendicitis.

In coping with these conditions those who retain their faith in modern surgical principles can not consistently recommend delay in operative measures, unless it can be satisfactorily explained just why—in this particular instance—they should deviate from a generally accepted law of surgery. I take it that the advantage of any departure from general principles should be clearly proven by abundant and substantial evidence before an exceptional plan be adopted, and that in the absence of such proof the safer plan would be to follow the rules of surgery that hold good in other parts of the body.

It is asserted by a majority of those who oppose immediate operation in all cases, that this infection had best be left within the abdominal cavity, unless it is apparent that the disease has not extended to or beyond the outer coat of the appendix; or that a local abscess has formed, with walls of requisite strength (in which case the abscess is opened, but the appendix is not removed if it form a portion of the abscess wall), or that all acute symptoms have subsided without pus formation, viz., between the attacks. They maintain that by thus limiting their operative procedures they lessen the danger of post-operative general peritonitis. They also claim that as for various good reasons they operate less frequently, they have fewer distressing post-operative sequelæ, less suffering and hospital expense, with equally as good results as those who operate promptly. Moreover, many assert that their experience and such clinical testimony as they can gather go to prove that 75 per cent. of all cases do as well as or better when trusted to nature than when treated surgically. The proofs offered in sup-

port of these opinions are largely made up from personal experiences, statistics, quotations from authorities and the testimony of patients.

The chief reasons for operating promptly in appendicitis, regardless of the stage, character or extent of the disease, presence of pus or tumor, or state of the pulse or temperature, may be briefly stated. First, such a course is in harmony with the generally recognized law that the presence of infected, devitalized tissue and pus in the human body is an indication for its removal by the most direct and safest route.

Second, as in this region nature's reparative methods involve the formation of more or less dense and extensive bands of adhesion which may impair or annul the functions of nearby vital organs, this mode of repair should not only be interrupted early, but should be followed by the breaking up of all adhesions and the removal, as far as possible, of all debris.

Third, if this course was pursued in all cases as soon as the diagnosis was made, experienced operators would not expect the mortality to exceed 2 per cent. Moreover, the 98 per cent. or 99 per cent. would be free from the apprehension of future attacks and the distressing effects of bowel, omental and mesenteric adhesions. Such results are believed to be infinitely better than those of any other plan of treatment.

Fourth, prompt operators believe that complete work is attended by less immediate danger and gives better ultimate results, while one of the rules of the delay operators is to leave the abscess wall intact, and frequently the gangrenous appendix is a part of this wall. Such incomplete work promises an imperfect result even if the patient lives.

Fifth, even if certain stages of the morbid process were known to present more favorable conditions for operative procedures we have no means, with our present knowledge, of recognizing these various stages or even of assuring ourselves that they will ever occur. *For it is impossible to accurately determine the exact pathologic changes taking place under a rigid or distended abdomen, by any combination of local or general signs or symptoms.* Few men of experience today would care to stake their professional reputation or their patients' lives upon their ability to discover a protruding enterolith about to escape into the peritoneal cavity, or to determine the exact strength of every part of an abscess wall. Yet those who wait accept for themselves and their patients these chances; for upon the safe imprisonment of this enterolith or other infection, and the maintained strength of this wall during their period of waiting depends the life of their patient.

In reply to the remaining statements of the oppositionists the prompt operators declare, first, to advise that operation be done before the disease has extended beyond the appendix is *equivalent* to operating at the earliest possible moment after a diagnosis is made; second, to operate between attacks is an admission that the patient has been unnecessarily exposed to the dangers of previous attacks, and to choose this time is only better than to wait for future attacks; third, it is unreasonable to suppose—if an operation is needed at all—that neglect, delay and incompleteness are the factors likely to eliminate post-operative or other complications and obtain better results than from prompt, complete work; fourth, their death rate can not be computed and must of necessity be a matter of guess work since many of their so-called cured patients still carry within their abdomens the rem-

nants of a disease which may light up at any moment; fifth, it is admitted that 75 per cent. of all cases of appendicitis do not die during an attack, even if not treated at all, but we are surely not justified in accepting a plan that results in the imperfect recovery of 75 per cent., when at our disposal is a plan that insures the complete recovery of 98 per cent.; sixth, it is inconsistent to expect that a mortality which is conceded to be due to "too late operation" will be reduced by a treatment that means further delay.

Furthermore, it is maintained that the evidence supporting the claims of those opposed to immediate operation, while not lacking in amount, is not of a character to lead us to depart from the general laws of pathology and surgery. The testimony of patients, the report of clinical observations by competent men, statistics, and even the unsupported opinions of honest, experienced men, have a relative value, but when in opposition to the teachings of pathology that value is very much less than when it is in confirmation of such teachings.

The testimony of patients, like that of all unqualified witnesses, is almost always unreliable. Then, too, we get only the testimony of the living, who naturally feel bound to testify to the efficiency of any treatment connected with their recovery. The fatal cases might tell a very different story if they could reappear upon earth. The clinical observations of competent men certainly deserve some consideration, but we should remember that these observations to be of much value must extend over a period of several years in each case, or be strengthened by the assurance that no remnants of diseased tissue remain in the abdominal cavity. Unless the appendix be removed, the fair way to report a recovery from one attack would be something like this: "This patient has survived an attack of appendicitis, but we have every reason for believing that he will always be in danger of future attacks until the appendix is removed, and each attack renders the next one more likely to occur and the operation more difficult." Let each of those who have faith in the teaching of clinical experience ask themselves the following questions: How many operations have I seen that in my own judgment were done too early? How many have I seen that proved to be too late? How many deaths and how much suffering has come under my observation that I honestly believe could have been prevented by timely and proper operations for appendicitis? Which of these chances shall I give my patient?

Statistics that include a large number of cases, with a description of the specimen removed, have a decided value, but no statistics, however voluminous, can be very convincing if they report under the head of recoveries, cases that still carry within their abdomens the original cause of the disease liable at any moment to light up a serious, perhaps fatal inflammation? The unsupported statements of so-called authorities are often quoted to bolster up this or that view of the treatment of appendicitis. But this question has been prominently before the profession for consideration a number of years and such arbitrary statements, unless they appeal to our reason and common sense, can not, or at least should not, materially influence us either for or against operative interference.

The above statements, to my mind, outline the chief points of this controversy that are deserving the consideration of those who are studying this question, not for the purpose of defending a pet theory, but in

the hope of deciding upon a treatment for appendicitis that shall promise the most for their patients in the saving of lives and suffering. It is customary, however, to introduce into these discussions other objections to the immediate operation, to which I will now make the briefest possible reference, for I believe that they should have little or no weight in influencing our conclusions. The assumption that a prompt operator advocates a laparotomy for any and all right-sided pains is as absurd as the belief that an infective inflammation can originate in the pericecal cellular tissue. It would appear to me quite immaterial whether what seems to us the best plan of treatment for a dangerous disease be named "radical" or "conservative," or whether those who propose or practice it be called "extremists" or "old fogies," "seekers after notoriety" or "arm-chair theorists." It can not concern the patient or doctor whether the plan of treatment be of ancient origin or the latest product of modern thought so long as it is effective. It can not be important whether it gives nature or surgery the leading or subordinate part in the cure so long as it promises the best results. Nor can I believe that we should be induced to advocate or practice an inferior treatment in order that poorly qualified and inexperienced men may safely employ it.

It has been said that to be known as one who always operates in appendicitis means to forfeit a certain amount of prestige and popularity with the public. This, if true, is the public's misfortune, I think, and it should rest with them to correct it. "Wholesale laparotomizing," "mutilating operations," "epidemic of ovariectomies" and other similar, meaningless and extravagant expressions are rarely found in any logical argument. Neither these nor any other unfair reflections upon our ability or sincerity should deter us from pursuing that course which our best judgment dictates. In appendicitis we have a condition, not a symptom nor a group of symptoms, to treat; this condition is an infection of the appendix and perhaps the surrounding structures, which when treated medically or left to nature has been shown to have a death rate in first attacks of 10 per cent. and an ultimate death rate of 25 per cent. The application of the same surgical principles that hold good in other parts of the body, viz., the prompt and complete removal of the infection promises a perfect recovery in 98 per cent. of all cases. The question is whether any treatment involving delay in the removal of this infection promises to reduce this 2 per cent. mortality. The waiting for a more favorable time to operate means, as I comprehend it, the subjecting our patients to ever-present real dangers while we wait for those fancied (at least unproven) favorable conditions which may never arise, and which, should they arise, we are unable to recognize, all for the purpose of doing a more or less incomplete operation that must promise a proportionately more or less imperfect result.

Eye-Strain.—Dr. Aaron Howell in the *Medical Bulletin* (Vol. xx, No. 4), gives the following as symptoms of eye-strain: Pain in the temporal region and in the back of the head and neck; red eyelids, also an inability to see at a great distance or to read at a long time; blurred vision, strabismus, a tendency to photophobia, twitching of the eyelid, along with sick-headache and dizziness when shopping, riding or attending places of amusement. He refers to chorea and other neuralgic symptoms as a possible outcome. The remedy lies in the proper adjustment of lenses by a painstaking and intelligent adviser.

THE TREATMENT OF INOPERABLE SARCOMA WITH THE MIXED TOXINS OF ERYSIPELAS AND BACILLUS PRODIGIOSUS.

IMMEDIATE AND FINAL RESULTS IN ONE HUNDRED AND FORTY CASES.

Presented to the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1908.

BY WILLIAM B. COLEY, M.D.

ATTENDING SURGEON TO THE NEW YORK CANCER HOSPITAL; ASSISTANT SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED. NEW YORK, N. Y.

(Concluded from page 395.)

The remaining personal cases worthy of special note will be found in tabulated form.

HISTORY OF THE MORE IMPORTANT CASES SUCCESSFULLY TREATED BY OTHER SURGEONS.

Case 1.—Inoperable sarcoma of pectoral region and axilla. Entire disappearance after seventy-eight injections. Patient perfectly well two and one-half years later.

This case is of the greatest interest, for it alone, unsupported by a single other case, would prove the specific action of the toxins.

This case, female, aged 42 years, was a patient of Drs. M. Storrs and R. H. Griswold of Hartford, Conn., and was treated by them under my direction. Her paternal grandmother died of cancer of the breast. There was no specific or tubercular history. The patient had been well up to October, 1895, when she noticed a lump in the left pectoral region. It grew rapidly and soon extended into the axilla. On Dec. 15, 1895, it had become so large and adherent to the axillary vessels that after a consultation of several prominent surgeons it was considered inoperable. A portion was removed and examined microscopically by Dr. R. Griswold, and the diagnosis of spindle-celled sarcoma was made. The diagnosis was further confirmed by Drs. Dunham and Buxton, pathologists to the New York Cancer Hospital, and finally by Prof. Wm. Welch of Johns Hopkins University. Seventy-eight injections of the mixed unfiltered toxins were given during the next three months, and at the end of this time the tumor in the pectoral region and axilla had entirely disappeared and the patient had regained her normal weight, having lost twenty-four pounds since the appearance of the disease. The patient was presented by me before the New York Surgical Society in November, 1896, in perfect health without a trace of tumor or induration in breast or axilla. She is still perfectly well, with no sign of recurrence, two and one-half years later.

Here we have a rapidly developing and hence highly malignant sarcoma, pronounced inoperable by four surgeons, the diagnosis confirmed by three pathologists of the highest reputation, and moreover, the type of tumor, one that Professor Welch states cannot be mistaken for anything else, entirely disappear under nothing but the injections of these toxins, and, more than all, remain well for nearly three years.

Case 2.—Inoperable spindle-celled sarcoma, involving the palate and fauces; entire disappearance under the mixed filtered toxins, the patient well and free from recurrence four and a half years later. This case was treated by Dr. Walter B. Johnson of Paterson, N. J. I saw the patient, in consultation, before the treatment was begun, in October, 1893, and can bear witness to the desperate condition that existed. The diagnosis of spindle-celled sarcoma was confirmed by careful microscopic examination, although the condition was so typical of malignant disease that the clinical diagnosis was practically certain. Improvement was at once evident, and the growth steadily disappeared until no trace remained. The patient has continued in perfect health up to the present time, four and a half years after the treatment.

A full report of this case, with illustrations, may be found in the *Medical Record* of Nov. 17, 1894.

Case 3.—Spindle celled sarcoma of the calf of the leg; entire disappearance under twelve weeks' treatment with the mixed toxins. Case No. 1, of Dr. L. L. McArthur, Attending Surgeon, St. Luke's Hospital, Chicago, Ill. The patient, female, aged 40 years, entered St. Luke's Hospital in the spring of 1894, for a removal of a tumor of the leg. Operation showed the tumor to spring from the dense fascia covering the muscles and calf. Although a very radical operation was performed, recurrence was regarded as probable, in the event

Table of personal cases in which the sarcoma disappeared, entirely or nearly, with final result.

No.	Sex, age.	Date.	Nature of Disease.	Treatment.	Result.	Remarks.
1	M., 35	May 4, 1891.	Recurrent spindle-celled; neck and tonsil (inoperable).	Repeated injections; living bouillon cultures, erysipelas, four months.	Tumors nearly disappeared; general health restored.	Well six years later.
2	M., 40	April, 1892.	Round, oval- and spindle-celled; back and groin (inoperable).	Living cultures; later, mixed toxins. (L.)	Entire disappearance; well three and one-fourth years.	Recurred in abdomen; fatal.
3	M., 17	Jan., 1893.	Spindle-celled; abdominal; wall and pelvis (inoperable).	Mixed toxins, filtered. (L.)	Entire disappearance.	Well May, 1898, five years.
4	F., 29	Oct., 1893.	Spindle-celled; abdominal wall (inoperable).	Mixed toxins, filtered and unfiltered. (B.)	Entire disappearance.	Well June 1, 1898, four and one-half years.
5	F., 17	Jan., 1894.	Recurrent spindle-celled; popliteal space and leg.	Toxins, unfiltered and filtered. (B.)	Entire disappearance, 1½ years; recurred later; amputation; further recurrence in gluteal region; treated with toxins up to present time.	Well June 15, 1898.
6	F., 34	June, 1894.	Inoperable epithelioma of chin, lower jaw, floor of mouth.	Toxins, unfiltered, three months.	Disappearance.	Well four years.
7	F., 16	June 23, 1894.	Inoperable spindle-celled sarcoma of chest wall.	Toxins, unfiltered, four months. (B.)	Entire disappearance.	Perfectly well June 23, 1898.
8	M., 24	March, 1894.	Very large chondro-sarcoma; ilium.	Toxins, unfiltered, six weeks. (B.)	Disappearance; recovered general health.	Recurred, 7 months; died one year later.
9	F., 27	Oct., 1894.	Round-celled sarcoma; mesentery and gall bladder.	Toxins, unfiltered, five months. (B.)	Disappearance.	Well three years later.
10	M., 38	May 11, 1895.	Inoperable sarcoma; sacrum (clin. diagnosis).	Toxins, unfiltered, six months. (B.)	Entire disappearance.	Well three years later.
11	F., 20	Feb. 18, 1896.	Recurrent spindle-celled sarcoma of hand.	Toxins, unfiltered and filtered, two months. (B.)	Disappeared two months.	Slight recurrence two years later; yielded to further treatment.
12	F., 18	Jan. 17, 1897.	Inoperable spindle celled, of abdominal wall.	Toxins, unfiltered, six weeks. (B.)	Entire disappearance.	Well May, 1898.
13	F., 5	Feb., 1897.	Recurrent round-celled; lower lip.	Toxins, unfiltered, six weeks. (B.)	Disappearance.	Well June 1, 1898.
14	M., 40	Aug., 1897.	Recurrent spindle-celled; parotid and neck.	Toxins, unfiltered, three months. (B.)	Entire disappearance.	Well June 1, 1898.
15	F., 40	Nov., 1895.	Spindle-celled; intra-abdominal.	Toxins, unfiltered, 6 weeks; 2 months; 2 months. (B.)	Entire disappearance; recurrence; later nearly disappeared.	Well November, 1897.
16	M., 14	Apr. 10, 1897.	Rapidly growing inoperable sarcoma of iliac fossa (clin. diag.).	Toxins, unfiltered, several months. (B.)	Very rapid improvement; tumor disappeared.	Well June 1, 1898.
17	F., 32	Jan., 1897.	Thrice recurrent sarcoma of the parotid; mixed-celled.	Toxins, unfiltered and filtered; several doses; six months. (B.)	Marked decrease in size; nodule excised.	Well June 23, 1898.
18	F., 59	Jan. 20, 1895.	Angio-sarcoma; recurrent; inoperable; breast.	Erysipelas and B. prodigiosus; serum 6 mos.; toxins filtered, few weeks. (B.)	Decrease in size; excision.	Well May, 1896.
19	M., 37	Nov. 4, 1894.	Eight times recurrent; spindle-celled sarcoma of chest wall (soft parts).	Toxins, unfiltered and filtered, with introductory small doses; 3½ yrs. (B.)	Marked inhibitory action; two or three small nodules removed.	Well June 1, 1898.
20	M., 55	June, 1893.	Large inoperable round-celled sarcoma of iliac fossa.	Toxins, unfiltered and filtered; at intervals; nearly one year. (B.)	Tumor nearly disappeared.	Well one year later, when lost sight of.
21	M., 32	Nov., 1895.	Large, inoperable, recurrent, tumor of upper lip. Diagnosis: Fibro-angelioma.	Toxins, unfiltered, one month. (B.)	Tumor disappeared.	Well two years later.

(B.)—Prepared by Dr. B. H. Buxton. (L.)—Prepared by Dr. Alexander Lambert.

of which amputation was advised. Seven months later, September, 1894, the patient returned to the hospital with a local recurrence the size of half an egg bulging from the calf of the leg. Inasmuch as the patient was several months pregnant, it was thought best to try the effects of the mixed toxins before resorting to amputation. The treatment was continued for twelve weeks with the result that the tumor entirely disappeared. Microscopic examination showed the tumor to be a spindle-celled sarcoma. The patient remains well at present, three years afterward.

Case 4.—Osteo sarcoma of the lower end of the radius, three times recurrent; entire disappearance of the tumor under three months' treatment with the mixed toxins. Case No. 2 of Dr. L. L. McArthur. This patient, adult, male, was admitted to the Michael Reese Hospital for recurrence in the cicatrix of a bony tumor situated in the lower end of the radius. The patient stated the growth had been pronounced sarcoma by Dr. C. Fenger. Amputation having been refused, the tumor had been removed as thoroughly as possible. Four months later recurrence followed and a second operation was performed by Dr. Edmund Andrews of Chicago. The original diagnosis was confirmed. Rapid recurrence followed. A third surgeon, Dr. D. A. K. Steele, was consulted, and again amputation was advised and refused. The patient then consulted Dr. McArthur, who regarded the diagnosis as undoubtedly correct and also advised amputation. The patient absolutely refused operation, and under these conditions Dr. McArthur agreed to try the effect of the mixed toxins. The treatment was begun in April, 1895, and the injections were kept up for three months, with the result that the tumor had entirely disappeared at the end of this time. The patient has remained well up the present time, June, 1898; Dr. McArthur states there has been no recurrence. Although no microscopic examination was made in this case, the fact that the tumor promptly recurred after several operations, renders the clinical diagnosis of such well-known surgeons scarcely open to doubt.

Case 5.—Osteo-sarcoma of tibia, round celled (giant); three months; treatment with the mixed toxins; entire disappearance; well three years afterward. Dr. John E. Owens of Chicago reported the following successful case before the Illinois

State Medical Society, May 1, 1897: The patient, a boy aged 7 years, received an injury to his leg in July, 1894. In December, 1894, a tumor appeared at the site of the injury in the upper portion of the tibia. In March, 1895, an exploratory operation was performed showing a tumor involving the medullary canal. Microscopic examination was made by Dr. E. R. LeCount, Pathologist to Rush Medical College. His report showed the tumor to be a round-celled myeloid or giant-celled sarcoma. "On account of the very high vascularity," he stated, in his report, "judging this to be a rapidly growing tumor, its malignancy is unquestioned." Amputation of the thigh was advised and, in fact, everything was prepared for operation, when Dr. Owens, at my suggestion, decided to try the toxins for a brief period. The treatment was begun April 10, 1895, and continued until July 10 at intervals of one to two days. The affected leg gradually returned to its normal size, the tumor disappeared; and in a recent letter, dated June 10, Dr. Owen states that the patient is still in good health, free from recurrence, more than three years afterward.

Case 6.—Extensive inoperable, intra-abdominal sarcoma, successfully treated with the mixed toxins. Case of Dr. Herman Mynter of Buffalo: a full report of which may be found in the *New York Medical Record* of February, 1895. The patient was a girl, 12 years of age. There was a history of local injury two or three months prior to the development of the tumor in the abdomen. The condition of the patient when the treatment was begun was desperate. Diagnosis was confirmed by exploratory laparotomy, and microscopic examination of a portion of the tumor showed the growth to be a spindle-celled sarcoma. The tumor entirely disappeared and the patient, according to a letter from Dr. Mynter, dated May 25, 1898, is in good health at present. It is very important to note that this cure was effected through the systemic action of the toxins, all of the injections having been made in the thighs. The duration of treatment was six weeks: large portions sloughed off and came away through the abdominal incision.

Case 7. Inoperable spindle celled sarcoma of the uterus, successfully treated with the toxins. Case of Dr. R. M. Stone, Omaha, Neb. My former paper contained a brief reference to this case, which was subsequently published in full in the

TABLE OF CASES TREATED BY THIS METHOD BY OTHER SURGEONS WITH COMPLETE OR PARTIAL SUCCESS.

No.	Reference.	Sex, age.	Date.	Nature of Disease.	Treatment.	Results.	Remarks.
1	Johnson, W. B., N. Y. Medical Record, Nov. 17, 1891.	M., 16	Oct. 31, 1893.	Very extensive spindle-celled sarcoma of palate and pharynx, extending to vocal cords.	Toxins filtered; 3 months' treat. (local). (B.)	Entire disappearance . .	Well May, 1898, 4 1/4 years later.
2	Mynter, Herman, N. Y. Medical Record, Feb. 1895.	F., 12	July 22, 1891.	Very extensive inoperable, spindle-celled intra-abdom. sarcoma, involving mesentery, omentum and cecum.	Toxins filtered; 2 months; in thigh.	Entire disappearance . .	Well June 1898, 4 years later.
3	McArthur, L. L., Chicago Med. Record, 1895, p. 120, and pers. communication.	F., 40	Sept., 1894.	Recurrent spindle-celled sarcoma, calf and leg.	Toxins unfiltered, 12 weeks. (B.)	Entire disappearance . .	Well May, 1898, 3 1/2 years.
4	Ibid. Personal com.	M., adult	May, 1895.	Three times recurrent sarcoma of radius; clin. diag., amputation advised by Dr. Christian Fenger.	Toxins unfiltered. (B.)	Entire disappearance . .	Well, 3 years
5	Ibid. Personal com.	F., 5 1/2	1895.	Round-celled sarcoma of antrum and pharynx and neck.	Toxins unfiltered. (B.)	Gained in weight from 37 to 69 pounds; tumors disappeared.	Later, fatal recurrence.
6	Owens, J. E., Prof. Surg. N. W. Univ., Chicago; New Orleans Medical and Surg. Journal, July, 1897.	M., 7	Apr. 10, 1895.	Typic (round) giant-celled sarcoma dept pathology, Rush Med. College.	Toxins unfiltered. 68 injections. (B.)	Entire disappearance; gen. health improved.	Well May, 1898, 3 years.
7	Barber, C. R., Syracuse. Personal communication.	M., 35	1894.	Very extensive intra-abdominal sarcoma, recurrent, inoperable; mesentery and omentum; no microscopic examination.	Toxins unfiltered.	Immediate and rapid improvement; entire disappearance of tumors; gained 40 lbs. in weight.	Well 4 years later.
8	Storrs, M., pers'l communication. N. Y. Surg. Soc. Report Annals Surg., 1897.	F., 42	Dec., 1895.	Inoperable spindle-celled sarcoma of pectoral region and axilla.	Toxins unfiltered. seventy-eight injections. (B.)	Entire Disappearance . .	Well June 1, 1898, 2 1/2 years later.
9	Czerny, Heidelberg, Munich Med. Woch., 1895.	M., adult	1895.	Round-celled inoperable sarcoma of parotid, size of fist.	Toxins unfiltered. 18 injections.	Tumor reduced to insignificant nodule, easily excised.	No recurrence, nearly one year later.
10	Stone, R. M., Med. Record, November, 1896.	F., 40	Dec., 1895.	Spindle-celled sarcoma, uterus; recurrent.	Toxins unfiltered. 3 months. (B.)	Entire disappearance . .	Patient well 2 1/2 years later.
11	Packard, Horace, Prof. Surg. Boston Uni., "Five Years in Surgery," also personal com.	F., 39	Aug., 1895.	Recurrent spindle-celled sarcoma of parotid.	Toxins unfiltered. 8 months. (B.)	Almost entirely disappeared, remaining small nodule excised Oct. 16, '95.	Well May, 1898, 2 3/4 years.
12	Ibid.	F., 15	May 4, 1896.	Inoperable endothelial sarcoma of pelvis.	Toxins unfiltered. several wks. (B.)	Entire disappearance . .	Well May, 1898, 2 years.

(B.)—Prepared by Dr. B. H. Buxton.

NOTE.—I have incomplete notes of another case of carcinoma of superior maxilla successfully treated.

New York Medical Record, 1896. The patient Mrs. B., aged 46 years, had lost fifteen pounds in weight, the right broad ligament was markedly infiltrated. The disease had progressed so far that hysterectomy was not to be considered—three surgeons who had seen her in consultation, regarding the case as absolutely hopeless. The toxins were begun on Dec. 6, 1895, and continued for two months with the result that the tumor as well as the infiltration of the broad ligament disappeared. The patient regained her usual health. She is at present, June 15, 1898 (two and a half years afterward), in perfect health without any evidence of recurrence. Upward of one hundred sections of the tumor were examined by Dr. W. R. Lavender, Professor of pathology to the Omaha Medical College, who made the diagnosis of spindle-celled sarcoma.

Case 8.—Inoperable sarcoma of the parotid successfully treated with the toxins, Case No. 3 of Dr. Packard. This case has been briefly reported by Dr. Packard in his "Five Years Work in Surgery," published in 1896. The tumor had recurred one year after previous operation. Further operation seeming hopeless, the injections of the mixed toxins were begun in May, 1895, and continued for several months. The tumor gradually decreased in size until only a small nodule remained. This was excised, and without further treatment the patient has remained in perfect health up to the present time, upward of three years.

Case 9.—Intra-abdominal sarcoma successfully treated with the toxins.—Dr. Packard's case No. 2, Mrs. W., aged 55 years, was admitted to Newton Hospital on April 14, 1896. Five years previously an abdominal hysterectomy had been performed. The stump was treated externally. Several weeks before her admission to the hospital in April, 1896, a sinus formed in the region of the old scar. On May 13 an exploratory operation was performed under ether, and a large, friable mass was discovered in the pelvis, suggesting malignant disease. Portions were removed and examined by Dr. Batchelder, who pronounced the growth to be sarcoma. The tumor was very vascular. For some time afterward there was marked tendency to hemorrhage and a constant fecal discharge from the sinus. On May 22, one minim of the mixed toxins was injected into the skin in the vicinity of the sinus. The dose was gradually increased up to 15 minims daily without any increase in pulse or temperature. The treatment was discontinued for two weeks and resumed in July, and continued in slightly increased doses until the early part of August, when the patient was discharged. She had gained markedly in strength and general health, and the fecal fistula had closed and the other abdominal symptoms disappeared. She returned to her home in a neighboring State and one year later reported herself well.

Case 10.—Spindle-celled sarcoma of the omentum successfully treated with the toxins.—Dr. Horace Packard of Boston, has recently sent me the following notes: The patient, male, 58 years of age, was referred to Dr. Packard early in 1898 for the surgical treatment of a painful, movable abdominal tumor, located to the left and a little above the line of the umbilicus. He had emaciated progressively, was able to take but little nutriment, and pain had become constant and excruciating. Exploratory incision was made and there was found a malignant growth of the omentum about four to five inches in length, two to three inches in breadth. There were several secondary nodules in the vicinity. A portion of the tumor was removed for microscopic examination and the wound closed. The specimen removed showed the growth to be a spindle-celled sarcoma. The patient was immediately placed upon the unfiltered toxins, which were continued, with occasional intervals, for three months. Although the doses were small (1 to 2 minims) the reactions were severe, causing marked prostration. After the treatment had been continued for a month, it was allowed a respite of four weeks. The patient's general condition was vastly improved and the tumor had appreciably diminished in size; the pain had entirely left him and he looked and seemed well. When last seen by Dr. Packard the patient seemed in excellent health, and the tumor could be scarcely felt.

Case 11.—Inoperable spindle-celled sarcoma of the uterus, recurrent—entire disappearance within nine months after the treatment was begun. Patient of Dr. H. T. Williams of Rochester, N. Y. The patient, female, aged 37 years, Canadian by birth, married nine years, no children. Menstruation began at 16, regular and normal in amount. Dysmenorrhea for past twelve years. The patient was first seen by Dr. Williams, April 16, 1891. The patient noticed a growth in the abdomen six years ago, since which time it has gradually increased in size. Her health was fair. Diagnosis: uterine fibroid. May 31, 1891, abdominal median incision. Large smooth fibroid of uterus: sound passed nine inches. Numerous adhesions in view of which latter it was considered best not to hysterectomy but to try the effects of spaying. Both tubes and ovaries, which were large and cystic,

were removed as close to the uterus as possible. Catgut used to ligate pedicles. Recovery from operation without disturbance. Nov. 21, 1891, menstruation more regular and much less profuse. Uterine sound passed five inches. May 19, 1892, periods every four weeks and almost normal in amount; sound passed four and one-half inches. Patient had been gaining flesh. She was then lost sight of until March, 1896, when she again came to Dr. Williams complaining of pain in right side and saying that she felt another tumor. Examination showed a large, hard tumor about the size of two fists in right side of abdomen, and upon vaginal examination it appeared to spring from right horn of uterus. The tumor was not very movable and seemed to be attached to abdominal muscles. March 24, 1896, exploratory incision through abdomen revealed a large, elastic tumor apparently originating in right pedicle, extending into abdominal muscles and adherent to intestines. As operation would have had to be a very extensive one, involving the removal of a large amount of abdominal muscle with the growth and probably resection of the intestines, it was not deemed possible that the patient could survive it. A portion of the tumor was removed for microscopic examination, which showed it to be a spindle-celled sarcoma. The abdominal wound was closed with eight silver wire sutures and healed by first intention. The tumor increased rapidly in size and a month after exploratory incision it projected several inches above the surface of the abdomen. April 24, 1896, 3 minims of the mixed toxins of erysipelas and bacillus prodigiosus were injected into the center of the tumor. The reaction was very great, patient had a severe chill, went into collapse, and brandy with strychnia, with salt solution per rectum and hypodermically, were required before she rallied, which she did a few hours later. Temperature had risen to 106 degrees but after a few hours had dropped to 100 degrees and next day was normal, but patient felt very much exhausted.

April 28, 1896, 1 minim of the toxins was injected into the tumor about an inch below the point of first injection. The symptoms of April 24 were repeated, but less severe, the temperature rising to only 103 degrees. The patient declared she would rather die than have any more injections; however, she was finally persuaded to permit another injection of 1 minim of the toxins on May 1, 1896. Reaction was less severe, temperature reaching but 102 degrees. On May 5, 3 minims were injected, causing a temperature of 103 degrees and slight chill. On May 8 and 14, 3 minims were given and were followed by considerable reaction, but temperature was not high. May 18, 1896, 4 minims were injected, causing a very severe prolonged chill and a temperature of 105.4 degrees F. The patient felt extremely weak for some days afterward. After each of the previous injections a slight erysipelatous blush had appeared around the point of injection but disappeared after a few days. This time an area of three to four inches in circumference of bright red color appeared. Poultices were applied to it and in a few days it turned black in the center and a slough about the size of a silver half dollar came away, leaving a hole of two to three inches in depth in center of tumor. The patient positively refused to have any more of the toxins used. This opening discharged for several months but the tumor grew rapidly smaller. Eight months later it had entirely disappeared. The patient was examined by Dr. Williams one year later and no trace of growth could be detected: she has gained considerable flesh and felt well. She is at present June, 1898, two years later, in good health.

Case 12.—Intra-abdominal sarcoma successfully treated with the toxins. Case of Dr. Chas. R. Barber of Rochester. Patient, male, born in Germany, 35 years of age, well developed, began to have indigestion in October, 1893. In the spring of 1894 he began to emaciate rapidly, and shortly afterward a mass was found a little above and to the right of the umbilicus and settled in the epigastrium. In May, 1894, his weight had fallen from 180 to 125 pounds. On June 16, 1894, exploratory operation was performed by Dr. Barber. He states: "It proved to be a case of cancer—probably sarcoma, on account of rapid growth—of the omentum, involving the surrounding parts, forming attachments with the intestine, bladder and parietal peritoneum." A large portion of the cancerous mass was removed. The patient made a rapid recovery and for a few weeks seemed better. On August 1, six weeks later, the growth began to increase rapidly in size on the right side of the cicatrix and over the right lobe of the liver, involving the abdominal muscles. On August 25 a second operation was performed and apparently all of the diseased tissue removed. Recurrence very quickly followed in the same region and further operation was considered hopeless. Injections of the mixed toxins of erysipelas were begun; a distinct chill followed every injection, accompanied by a rise of temperature. Dr. Barber states: "I soon had the gratification of seeing the

tumor diminish in size and gradually disappear altogether." The patient regained his normal health and strength and has been working ever since. He was well and free from recurrence in June, 1897, or three years after treatment. Unfortunately, the portion of the tumor sent to the microscopist for examination was lost; yet the clinical history of the case, the very rapid development of the tumor and the rapid recurrence, make it almost impossible to doubt the correctness of the diagnosis of sarcoma.

Case 13.—Osteosarcoma of the fibula successfully treated with the toxins. The following is a brief abstract of a case just reported at the meeting of the North Carolina Medical Society, May, 1898, by Dr. J. C. Walton of Reidsville, N. C.

The patient, adult, female, was first seen in 1895, with a tumor enlargement in the region of the calf of the right leg. There was considerable pain and discomfort. The pain was first noticed in March, 1894, and the lump appeared in June, 1894. The swelling gradually increased in size and the tumor became more painful, until in the spring of 1895 she was unable to bear her weight upon the leg. Examination showed the calf of the leg to be the site of a large, hard, smooth, globular tumor, with distended veins over the entire surface. The leg measured over two inches more than the other. There was no involvement of the joint. The patient's general condition had been good up to a short time previous to the development of the tumor. As the growth increased in size, her general health failed, on account of the pain, loss of sleep and anorexia. A well-known Virginia surgeon had pronounced the disease sarcoma, and had advised amputation of the lower third of the thigh. Inasmuch as the patient absolutely declined operation, the injections of the mixed toxins were begun by Dr. Walton on May 18, 1895, the injections being made deeply into the tumor. The initial dose was one drop, which was gradually increased to four, but the patient was never able to bear more than this. The temperature reaction varied between 102 and 105 degrees, accompanied by the usual symptoms. The injections were kept up until August 1, or two and one-half months. The tumor had gradually become circumscribed, and in July had begun to soften and break down. On December 13 an incision was made and the broken down mass removed with a curette. The tumor was very vascular and the hemorrhage profuse. In December and January a second and third curetting was made and a large quantity of marrow-like, gelatinous substance, together with a portion of the shaft of the fibula, was removed. A severe hemorrhage followed a week after this operation. From this time on the patient's health rapidly improved, the cavity began to fill with healthy granulations and in a short time she was discharged cured. This was in January, 1896. Dr. Walton states that the patient is at present, May, 1898, in good health, able to walk without a cane, suffers no inconvenience except a little from the loss of bone, and presents a normal appearance.

In the discussion upon this case, Dr. Robinson, who had seen the patient, stated that there could be no doubt in the mind of anyone who had seen the case, that it was sarcoma. No pus had been found during the entire course of the treatment, and this, together with the fact that the joint was not involved, would seem to indicate beyond a doubt that the disease was sarcoma and not of tuberculous character.

Case 14.—Mr. C. Mansell Moullin, surgeon to the London Hospital, in a most complete paper read before the Harveian Society of London, on Feb. 3, 1898,¹ reviews the whole subject of the treatment of malignant tumors with the toxins. The paper shows a thorough familiarity with the literature of the subject, and his conclusions have the additional weight of being based upon an extended personal experience with this method of treatment. The toxins employed were in part prepared by the British Institute of Preventive Medicine and in part obtained from Dr. Buxton of the Loomis Laboratory of New York, and similar to those employed by myself. They were used in ten cases, with three successes and two deaths. In one of the fatal cases, Mr. Moullin states that the case was undoubtedly not a suitable one. The patient was a man over seventy years of age, with an enormous and very vascular sarcoma of the femur. His condition was very feeble, and during the month that elapsed before the fluid could be obtained his condition became much worse. The first injection was without result. The second, two days later, caused a rigor which was followed by such prostration that the patient never rallied. The tumor was a very vascular one, pulsating freely, and the injection on the second occasion in all probability entered directly into a vein. In the second fatal case the patient died from acute pyemia, under conditions curiously like those of a case recorded by Mr. Marmaduke Sheild.² In both cases the

fluid was carefully tested by a thoroughly competent observer and proved to be absolutely sterile. In both instances, another patient who was being injected from the same bottle, at the same time and even on the same day, experienced nothing more than the ordinary reaction. The explanation of death in these cases offered by Mr. Moullin is undoubtedly the correct one. In both cases the ulcerating parts of the tumor were full of pyogenic micro-organisms, probably staphylococci. It is well-known that micro-organisms that are comparatively harmless, either from the conditions under which they have been living or from the smallness of their number, may become intensely dangerous if they are associated with or aided by the presence of other organisms or the injection of other toxins. The staphylococci were there, inert or almost inert. The injections of the toxins, either by increasing their virulence or by diminishing the resistance of the tissues, or by both, were responsible for the pyemia that followed. Of the eight remaining cases one was a carcinoma of the breast which showed no change. Another was a lymphosarcoma of the groin in a young man who, after two injections, declined further treatment. A third was a similar growth in the neck of a man 65 years of age, which showed no effect from considerable doses of the toxins. Two improved slightly, and in three the tumors disappeared. The following is a brief abstract of these five cases:

Case 14.—(Moullin). A man, 28 years of age, was admitted to the London Hospital in November, 1895, with a tumor in the groin, which had been noticed for four weeks. The right iliac fossa was occupied by a firm swelling, fixed not fluctuating, rather tender on pressure, extending to within an inch of the median line and deeply on the inner surface of the pubes. The injections were begun in December, the initial dose being one-half minim, which was steadily increased to eight minims. Rigors occurred on several occasions. At first the tumor increased in size and the skin over it became red and tender; by the middle of January a diminution in size was plainly noticeable. Then it increased again concurrent with several rigors. After that there was a decrease in size until in March it had almost entirely disappeared. The treatment had been discontinued by the end of February, 1896. The patient's weight increased from 138 pounds to 145 pounds, and he was well two years later.

Case 15.—(Moullin). A man, 55 years old, admitted in November, 1896. Examination showed a large, irregular swelling of firm consistence not connected with the skin or abdominal muscles occupying the left flank. The tumor had first been noticed four weeks before. The injections were commenced in December, beginning with one-half minim and kept up until the end of January, 1897, causing several rigors. The growth continued to increase. At one time it appeared to be acutely inflamed. After that it slowly diminished in size until it could scarcely be felt. The patient was discharged in March, in a much better condition than when he entered, his general health being perfect. This case remained well up to the date of the paper, Feb. 3, 1898.

Case 16.—(Moullin). A man, 38 years of age, was admitted in October, 1895, with tumor of the hip. He had been sick for four months. The upper end of the thigh was occupied by an irregular swelling that filled up the space between the iliac spine and the trochanter, and moved with the limb. The iliac glands were enlarged. The limb itself was inverted, adducted and apparently shortened. Injections were commenced in October, the doses being increased rapidly up to nine minims, which produced rigor. After that several such doses were borne without effect until a third attack of rigor followed on injection of but five minims. The patient complaining of weakness the treatment was discontinued. The swelling of the hip decreased gradually. The gland disappeared. The movements of the hip became more free, and inversion and adduction were hardly noticeable. A year after his discharge there was no recurrence.

Case 17.—(Moullin). A woman, 29 years old, was admitted on the 7th of October, 1896, suffering from a tumor of the right temple. Six years prior to her admission a swelling had appeared over the root of the right upper canine tooth. This had gradually increased in size. In December, 1894, the right superior maxilla had been removed at the London Homeopathic Hospital. Microscopic examination had proved the growth to be a mixed round and small spindle-celled sarcoma. Three months before admission the patient had noticed a swelling in the right temporal region. This had slowly increased in size and caused her much suffering from shooting pains. The swelling was of very firm and uniform consistence and non-fluctuating. Injections with toxins obtained from the British Institute of Preventive Medicine were begun October 9. They were given into the arm in doses increasing from one-half minim to twelve minims, and continued almost daily. There

¹ The Lancet (London) Feb. 5, 1898.

² Brit. Med. Jour., January, 1897.

was occasional slight reaction but no rigor or headache, and the growth steadily increased in size. On November 7, three minims of a fluid sent over by Dr. Coley were injected into the tumor, causing a rise of temperature to 101 degrees, cold feet and vomiting. The next day a dose of five minims was injected, being followed by distinct rigor, headache, vomiting and pain in the back. The injections were continued daily and gradually increased to eight minims, each treatment being followed by a rigor. On November 15 the tumor had definitely altered its shape. The next day, the patient objecting to further injections into the tumor, nine minims were injected into the arm without effect. The following day, the patient, having given up hope of improvement from the treatment, left the hospital. Mr. Gordon Brown reports that after the patient left the hospital the growth increased in size involving the malar bone, causing considerable swelling in the zygomatic fossa and leading to exophthalmos. There was intense pain in the head. The eyeball protruded and sloughed away. In November the tumor had become much smaller, but there was an apparent recurrence in the left tibia. In December, 1897, Moullin found that the sarcoma at the outer angle of the orbit had disappeared entirely. There was a deep hollow in the temporal fossa. The eyeball was gone and the orbit empty. The left leg was much swollen and there was apparently a tumor in the upper part of the tibia.

Case 18.—Inoperable sarcoma of the breast successfully treated with the toxins.¹ I am indebted to Dr. J. A. Jackson of Sun Prairie, Wis., for the report of the following case: Female, aged 36 years, with sarcoma of the breast of seven years' duration. The patient was seen in consultation by Dr. C. Fenger of Chicago, in September, 1896, and the growth at that time was pronounced inoperable. The cervical and axillary glands were enlarged, and the disease was also thought to have involved the femur. Dr. Fenger counseled against operation, and advised the mixed toxins of erysipelas and bacillus prodigiosus. The treatment was begun on the 25th of September, 1896, and continued until October 2, the highest reaction being 100.5 per cent. The tumor softened and discharged slightly. On the 30th of September she had nausea and vomiting. The vomiting continued almost constantly until October 9th. The vomiting was only controlled by hypodermic injections of morphin. From this time on the tumor shrank up, the glands grew smaller, the ulcer healed and the appetite improved. On February 8, 1897, four months later, she had a well-marked attack of erysipelas of the face. After a few days it subsided, and the ulcerated surface cicatrized, leaving a smooth scar and the glands normal in both cervical and axillary regions. A metastatic tumor developed in the rectum about six months later which finally caused death.

Case 19.—Case of Dr. D. B. Hardenberg, Middletown, N. Y. (Unreported.) The patient, male, 48 years old; merchant. Family and previous personal history good. The patient first consulted Dr. Hardenberg April 21, 1897, giving the following history: Several months he had suffered from almost constant pain located in the left hypochondriac region. On April 10th the pain and disability had so far increased as to confine him to bed. Physical examination, April 21, showed a hard swelling in the left iliac region, firmly adherent to the left ilium and abdominal wall. The tumor extended one inch above the crest of the ilium, was sharply defined on its upper border, and extended nearly to the median line. Examination by the rectum, negative. The patient complained of constant pain, and in the evenings the temperature generally ranged between 101 and 101.5 degrees. In view of the duration of the tumor (3 to 4 months) and its close relation to the ilium, probable diagnosis of sarcoma with septic degeneration was made. May 1st, the temperature continued slightly increased, reaching 102.5 degrees, redness and signs of breaking down becoming apparent. The patient was etherized and a free incision made one and one-half inches above and parallel to Poupart's ligament. About two ounces of purulent fluid were evacuated, and a large sized rubber drainage tube inserted. The discharge was very moderate. The mass decreased in size, but the pain continued unabated. During the next four weeks persistent efforts were made by means of poulticing and the administration of alteratives to promote the breaking down of the tumor. At the end of this time the tumor had increased in size and was so firmly adherent to the ilium that it seemed to form part of it; the upper border was very sharply defined; the measurements of the tumor at this time showed that it extended three and one-half inches from the anterior superior spine toward the umbilicus, four inches toward the pubis. The case being regarded as hopeless, the mixed toxins were begun May 28, 1897, the initial dose being one-half minim. No reac-

tion followed. The second dose of 1 minim produced a marked chill and a temperature of 104 degrees. After the third injection a marked decrease in size was noted, the dimensions having become reduced by 1 inch. The toxins were continued in gradually increasing doses until June 18th. The tumor rapidly and progressively diminished in size until it finally disappeared. Two weeks later the patient had apparently recovered his usual health and was able to walk without difficulty, having been confined to his bed for three months.

In a letter from Dr. Hardenberg, dated June 1, 1898, he states: "The patient is now in excellent health, with no signs of recurrence." As regards the diagnosis, Dr. H. writes: "I regret that I did not remove a portion of the tumor at the time of the operation for microscopical examination, but I had not sufficient hope of a successful issue to be induced to do so. The clinical history, situation and general characteristics of the tumor are, I believe, good evidence of its nature. At all events, the toxins caused rapid disappearance of a trouble that neither time nor ordinary treatment made any impression upon."

This case bears a striking resemblance to the successful cases recently reported by Moullin: in fact, there is less reason to doubt the diagnosis of this case than there was in those of Moullin.

Case 20.—Inoperable recurrent sarcoma of the ovary; marked improvement under the mixed toxins: rapid necrosis of entire tumor; death from septic absorption (unreported). Case of Dr. M. L. Harris, Chicago, Ill. The patient, American, female, aged 31 years, unmarried. Family history good. In June, 1897, she first noticed discomfort and slight pain in the lower front of abdomen. Four weeks later the family physician discovered a tumor in the lower part of the abdomen; it grew very rapidly and caused disturbance of the bowel. Examination, Sept. 18, 1897, showed the following: General condition of the patient fair, heart and lungs entirely normal, abdominal tumor arising from the pelvis, extending midway from symphysis pubis to umbilicus, lying somewhat more to the right side, movable, but not freely so. The uterus was crowded anteriorly and slightly to the left side, moving with the tumor, which was solid. Operation, Sept. 22, 1897, median celiotomy. Large solid tumor originating from the right ovary, adherent to uterus, rectum and pelvic wall, was found. Uterus and appendages removed with the tumor. Gauze packing was necessary to arrest hemorrhage. Microscopic examination of the tumor showed it to be a large, round-celled sarcoma. The patient recovered well from the operation. October 11, difficulty in moving bowels. Examination per rectum showed a recurrent mass in the posterior part of the pelvis pressing upon and involving the anterior wall of the rectum. October 13, tympanites became marked; no bowel movement was attainable. October 14, tympanites intense. Rectum high up seemed virtually occluded by the pressure of the rapidly growing, recurrent mass. Colotomy was considered with a view of giving temporary relief, yet it seemed dangerous from the extreme distention. No gas passed per rectum. It was finally decided to try the mixed toxins. October 14, at 4:30 p.m., 1 minim was injected into the arm; no apparent reaction. October 15, at 6:30 p.m., she expelled gas with some fecal matter. At 10:30, 2.5 minims of the mixed toxins were injected into the arm. No reaction. October 15, 4 p.m., 5 minims of the mixed toxins were given; temperature arose 1.5 degrees; bowels moved and considerable gas was expelled. The patient rested comfortably. October 16, at 11 p.m., another 10 minims; 1.6 degree rise, reaction, temperature 100. Bowels moved several times; gas freely expelled. Tympanites had practically disappeared. (Dr. Harris adds: "I could only attribute the lessening obstruction of the bowel and the disappearance of the tympanites to the effect of the toxins, causing the shrinking of the tumor.") October 18, lower angle of abdominal wound reopened so that the tumor could be seen. It was found to be the size of an average coconut. The toxins were thereafter given daily in doses up to 40 minims, the injections always being made subcutaneously in the arm. Very little reactions followed the injections. October 31, pulse was 86; temperature 98; bowels moved freely, almost naturally. November 6, it was noticed that the tumor had become black and was evidently sloughing, fecal matter coming through the wound. November 8, the tumor remained black and sloughing, and there was a bloody watery discharge. The patient now began to show symptoms of septic absorption from the immense sloughing, which involved the entire mass and opened into the rectum. The patient grew weaker, dying November 15.

Dr. Harris states that all injections of the toxins were made in parts remote from the tumor, in the arms and sides of the body; no injection was made into the tumor itself. Only once

¹ This case was briefly reported at the meeting of the Central Wisconsin Medical Society, March, 1897, by Dr. L. B. Lewis.

did anything like a reaction follow the injections. On October 26, after an injection of 24 minims, there was a chill with a temperature of 103 degrees, pulse 150. A few days before the tumor began to slough the patient was sitting up in bed daily, eating fairly well and having good bowel movements. This unpublished case is reported at some length for the reason that it has an important bearing upon the question of the systemic action of the toxins; inasmuch as no injections were made into the tumor, it furnishes complete proof that the action of the toxins is systemic as well as local. It further shows the danger connected with the rapid breaking down of a large intra-abdominal sarcoma. Whether the result would have been different had the injections been given in smaller doses it is hard to say; it is possible that if the degenerative process had been slower the products might have been disposed of either by absorption or by external discharge, as happened in the preceding case of Dr. Mynter.

Case 21.—Recurrent spindle-celled sarcoma, intra-abdominal. The following case was treated by Dr. Frank H. Zabriskie of Greenfield, Mass., who has kindly permitted me to report it. The patient was a woman aged 43, with good family and personal history. In the latter part of 1895 she noticed a hard swelling in the lower part of the abdomen; this had steadily increased in size. In July, 1896, with the assistance of Dr. Zabriskie, I removed a large tumor, the size of a child's head, situated behind and to the right side of the uterus and apparently starting behind the peritoneum. Careful microscopic examination was made by the pathologist of the (Greenfield Hospital, who pronounced the growth a spindle-celled sarcoma. A specimen was examined independently by Dr. B. H. Buxton, Pathologist to the New York Cancer Hospital, and the diagnosis was confirmed. About four months after the operation a recurrent tumor of considerable size was found at the site of the primary tumor. This grew rapidly, and in November, 1896, the mixed toxins were begun by Dr. Zabriskie and continued three times a week for about three months. The tumor decreased markedly in size. In July, 1897, I examined her and found a hard tumor in the region of the left broad ligament, about the size of a goose egg. I advised another attempt to remove it by operation, but the patient would not consent. The toxins were continued by Dr. Zabriskie two or three times a week in moderate doses (not enough to produce a chill) and with occasional intervals of rest. In June, 1898, I again examined the patient and could find only the merest trace of the tumor which was present the year before. Her general health was perfect.

Case 22.—Multiple fibrosarcoma, successfully treated by very small doses of the toxins injected subcutaneously remote from the tumor. W. H. Battle (London *Lancet*, April 9, 1898, p. 998) presented before the Medical Society of London, on April 4, 1898, the following case:

The patient, male, aged 30 years, was admitted to St. Thomas Hospital, London, Dec. 21, 1897, service of Mr. McKellar. The patient was a well developed, muscular man, with a history of having had syphilis six months before; three or four months prior to admission into the hospital a lump had appeared in the right arm. The tumor was painful. Later, several other swellings developed in the arm and axilla. Still later a tumor appeared in the subclavicular region beneath the pectoral muscle. The movements of the arm became limited and the arm itself gradually became swollen. Two weeks before admission a swelling was noticed about the right clavicle and another just to the right of the sternum; the right arm was swollen and edematous; superficial veins were dilated and tortuous. The tumor above the clavicle was the size of a hen's egg, while below the clavicle there was an elastic tumor of considerable size, underlying the pectoralis major and pressing this muscle forward. The tumor was of irregular shape, fixed to the deeper parts, but did not involve the pectoralis. In the axilla were two glandular tumors, the size of tangerine oranges, with numerous others of smaller size. The patient's general condition was good. Iodid of potash was given for a time, without any improvement resulting. Portions were removed from the sternal and subclavicular tumors and examined by Dr. Jenner and Mr. Shattock, who pronounced the growth to be a fibrosarcoma with giant cells. Small doses of the mixed toxins of erysipelas and bacillus prodigiosus (one-half minim) were given every other day, injections being made, not into the tumors, but subcutaneously into the arm. The treatment was continued from January 21 to March 21, two months. Iodid of potash was discontinued on March 6. From March 21 to April 4 (the day the patient was exhibited) 1 minim of the toxins was administered every other day. Patient was much improved in general health, and examination showed only two small swellings remaining, one at the site of the sternal tumor, which was reduced to one-third its original size, and the other under

the clavicle had become only a flat, limited hardness in the costo-coracoid membrane above the pectoralis minor $1\frac{1}{2} \times 1\frac{1}{4}$ inches in area. The other tumors had disappeared.

This case is one of the most remarkable yet reported, for two reasons: first, it furnishes additional proof of the view maintained by myself, that the action of the toxins is systemic as well as local; second, it shows that most remarkable results can be obtained by means of very small doses without any of the dangers and discomforts that accompany the severe reactions.

Summary of results in cases of other men employing same method.—Of 35 cases in which the sarcoma entirely or nearly disappeared 10 were round-celled, 10 were spindle-celled, 5 were based on clinical diagnosis alone, 5 were based on clinical diagnosis and history of recurrence after operation, 4 microscopic examinations made, but type of sarcoma not given; 1 endothelial sarcoma.

Of these 35 cases 26 disappeared completely; 2 others decreased so much that only an insignificant node was left and this was easily excised (one of these cases was well three years, the other was well one year when last reported.)

Final results.—Of 10 cases of spindle-celled sarcoma in which the diagnosis was confirmed by microscopic examination, 6 were well two to four and three-fourths years after treatment, (3 of them over three years). Of the round-celled 2 were well one to three years; the case of endothelial sarcoma two years; of the 5 cases in which the clinical diagnosis of sarcoma was supported by a history of recurrence, 2 cases are well three years, 1 case was well two years. Of the cases that rest on clinical diagnosis alone, 3 are well two years, 2 are well one year. Of the total 35 cases 14 cases were well over two years, and 6 cases well over three years. In 2 of the 35 cases death occurred during the third and fourth week of treatment, after the tumors, —both round-celled sarcoma—had been entirely destroyed. In 1 case (Shields') death was due to pyemia of staphylococcus origin, the infection occurring at site where tumor had sloughed away. In the other case death resulted from septic absorption from too rapid necrosis of very large round-celled sarcoma in the pelvis—here also outside infection undoubtedly occurring. In one case recurrent sarcoma of neck and tonsil. The patient developed erysipelas of scalp, six months after beginning of treatment, when apparently cured of the sarcoma. The treatment with the toxins possibly rendered the patient peculiarly liable to accidental infection.

Recurrence after having once disappeared under the treatment.—In seven cases recurrence took place after the tumor had disappeared. In six cases this occurred within a year, in one case at the end of two years. Three of these cases were round-celled, one mixed-celled, one sarcoma of neck, (type of cell not given) and two sarcoma clinical diagnosis. In four of these cases the recurrence was local and in three metastatic; one in lunge, one in rectum, (primary sarcoma of breast in both cases) and the third (Moullin's case) regarded as a probable recurrence in tibia, the primary tumor having been in superior maxilla. A careful study of the case however gives one reason to believe that this swelling in the tibia was not a recurrence but rather an inflammatory tumor indirectly following the use of the toxins. Such swellings I have observed a number of times especially when using the living cultures, and in Moullin's case the tumor of the superior maxilla and orbit having sloughed out, infection could easily have occurred.

ANALYSIS OF PERSONAL CASES AND SUMMARY OF RESULTS.

Total number of cases treated, 140. Of these 84 were round-celled; 21 were spindle celled; 9 were melanotic sarcoma; 2 chondrosarcoma; 12 sarcoma (diagnosis confirmed by microscope, but type of case not given); 6 sarcoma (clinical diagnosis of inoperable sarcoma).

Round celled.—Of these 40, or slightly less than half, showed more or less improvement, as evidenced by decrease in size and cessation in growth. In the great majority of these cases the improvement was only temporary. In 2 cases, however, the tumor entirely disappeared, and in a third nearly disappeared. All of these cases were well when last observed, one having gone over three years, one a year and a half, and a third one year. A fourth became so much reduced in size that it was easily removed. The remaining cases of round-celled sarcoma showed very little, if any, effect from the treatment.

Spindle-celled.—Of the 21 cases of spindle-celled sarcoma, 10 disappeared entirely and all of the remainder showed marked improvement. Of the 10 successful cases, one was well 6 years (living cultures used in this case); one for 5 years, one for 4 years, one for $4\frac{1}{2}$ years, one for $1\frac{1}{2}$ years, one for 1 year, one for 9 months. In 3 cases of spindle-celled sarcoma the disease recurred at intervals of 9 months to $1\frac{1}{2}$ years. In all of the cases the disease yielded to further treatment. Two are now

well, and the third, when last heard from, 9 months ago, was improving.

Melanotic sarcoma.—No case showed more than slight temporary improvement. It should be noted that Dr. George R. Fowler of Brooklyn has had one case of melanotic sarcoma of tonsil and fauces entirely disappear under the mixed toxins, but there was a recurrence two years later which proved fatal.²

Mixed-celled sarcomas.—Of these, one entirely disappeared and the patient remained well for 3½ years, when a recurrence took place in retroperitoneal region, which proved fatal in a few months; one became smaller, was removed and the patient is now well over one year; two other cases were improved and two unimproved.

Chondrosarcoma.—In one case—very large inoperable sarcoma of ilium—the tumor disappeared entirely and the patient was well for seven months. Local recurrence then took place, proving fatal.

Osteosarcoma, inoperable.—Clinical diagnosis of only one case; osteosarcoma of sacrum. Tumor entirely disappeared and patient well nearly three years later. One of ilium; tumor disappeared and patient well 1½ years.

One epithelioma of chin and floor of mouth, is well 4 years; one recurrent, inoperable fibro-angioma is well 2 years.

SUMMARY OF FINAL RESULTS.

In 24 cases, partial or complete disappearance of tumors was observed; in 16 cases this was complete. Of these 8 cases were well 3 to 6 years; 9 were well 1½ to 3 years; 4 are well at present, 9 months to 1½ years; 3 died of recurrence, which took place from 7 months to 3½ years after treatment.

The action of the toxins upon the different types of sarcoma.—It is evident from a study of the cases reported that the influence of the toxins varies greatly, according to the type of the sarcoma, being most marked in the spindle-celled, and least in the melanotic variety. It is a significant fact, and one of great importance from a pathologic standpoint, that more than one-half of the cases of inoperable *spindle-celled sarcoma* treated with the toxins have disappeared entirely, and every case showed a marked improvement. Of the cases of round-celled sarcoma about one-half showed more or less improvement, the other half failing to show any effect from the treatment. In many cases the improvement was but slight and temporary in character; the tumors at first showed decrease in size, a little later they remained stationary and then after a longer or shorter interval again increased in spite of the treatment. A considerable number of round-celled sarcoma have disappeared entirely and there is reason to hope for a permanent cure.

The melanotic variety, as I have said, is the least influenced of all. I have treated ten cases of melanotic sarcoma, and in no case was there more than a slight, temporary improvement. It is true that most of the cases were multiple and very far advanced at the time the treatment was undertaken; yet, in one case the injections were begun immediately after primary operation, as a prophylactic measure, but this did not prevent speedy recurrence. Were it not for the fact that there is a case of advanced melanotic sarcoma on record which was cured by accidental erysipelas I should look upon this variety as entirely hopeless. The varying action of the toxins upon these different types of sarcoma lends support to the opinion expressed by Bland-Sutton in his book on "Tumors, Innocent and Malignant," which is as follows: "The opinion that all varieties of cancers are due to one cause, assuming cancer to be the product of such agents as produce tubercle, glanders and actinomycosis, it is much more probable that under the term cancer, many tumors are grouped together on account of structural likeness, they have a widely different cause; and the same view holds good for sarcomata and epitheliomata."

Again, writing in 1892, the same writer states: "Sarcoma" is probably the scene of action of a violent and prolonged contest between irritant micro-organisms and leucocytes. I say probably, because, as has been already remarked, pathologists have not yet succeeded in isolating a specific bacteria for sarcomata in general. That such agents will soon be discovered is in the highest degree probable, because in recent years the list of infective granulomata is made at the expense of sarcomata. The structure, mode of growth, infective properties and manner in which these tumors destroy life, clearly coincide with what is positively known in regard to infective granulomata.¹

I will here repeat the opinion which I have expressed in an earlier paper, first in 1892, that I believe this curative action of the streptococcus of erysipelas and its toxins can only be explained on the ground that sarcoma is of micro-parasitic or infectious origin. Furthermore, I believe this action in itself furnishes very strong evidence in support of this theory. It is a well-known fact that the streptococcus of erysipelas exerts a powerful influence upon tubercular and syphilitic lesions, both due to a specific micro-organism, and as far as we know it has no effect upon any form of tumor not of infectious origin: unless we exclude sarcoma and carcinoma. Several links in the chain of evidence have been added during the past two years through the experiments of Juergens of Berlin, and more notably by the more recent researches of Roncali and Sanfelice of Italy. These experiments have been so convincing that so conservative and careful an observer as Dr. Roswell Park in his recent paper on the "Etiology of Cancer,"² read before the American Surgical Association, states: "Without going so far as to say that this can be done in every instance and that all cancers are necessarily of parasitic origin, one is justified by these results in at least maintaining that some cancers are positively of such origin. If upon this experimental ground one should infer that all cancers are parasitic manifestations he would do, as will be seen, little violence to the laws of evolution."

Space will not permit me to describe a number of other cases in which the injections of the toxins were followed by marked improvement, but I have given a detailed report of eight cases of sarcoma treated since the meeting of this Association in May, 1895, which totally disappeared under the injections. All save two were inoperable, and these two were both rapidly recurrent, amputation of the right arm being the only operation that could be offered in one, and extensive removal of the lip in the other. The diagnosis in seven of these cases was confirmed by microscopic examination, and in the eighth case the clinical diagnosis was beyond reasonable doubt. If a tumor of four months' growth, starting from the sacrum, can cause a loss of thirty-five pounds in weight, produce marked cachexia, severe lameness in both legs and agonizing pain, and yet be non-malignant, we have certainly discovered some new variety of benign tumor. Moreover, a substance which, injected subcutaneously, in regions remote from the tumor, causes almost immediate cessation of this pain, rapid return of appetite, an increase in weight of twenty-eight pounds in the short space of six weeks, with no other treatment, all this with the gradual decrease in size, and final disappearance of the tumor itself, while the patient con-

² Amer. Jour. Med. Sciences, August, 1898, p. 175.

¹ J. Bland-Sutton: "Evolution and Disease," London, 1892.

² American Journal of Medical Sciences, May, 1898.

tinues in perfect health three years after the treatment, such a substance must possess qualities sufficiently interesting and important to command our most serious consideration. Turning to the other seven cases in which the diagnosis was confirmed by microscopic examination, and in which the tumor entirely disappeared under the same treatment, have we not sufficient evidence to convince the most exacting critic that these toxins do have specific action upon sarcoma, which in a considerable number of cases, proves curative? In addition to my own, I have tabulated thirty-two cases of sarcoma treated by other surgeons, here and in Europe, with the same preparation of mixed toxins with complete or partial success. The successful cases have become so numerous and so well authenticated that the favorite explanation of the critics, "mistaken diagnosis," must now be abandoned. No one can seriously offer such an explanation and still retain a reputation for sound judgment and fair-mindedness.

I have been more than surprised to find surgeons for whose ability and judgment I have the highest regard, find it almost impossible to believe in the efficiency of the toxins of erysipelas, although they fully admit the beneficial and curative properties of accidental erysipelas in malignant tumors. The more we study the life history of pathogenic germs the more certain do we become that their influence upon man or animals is chiefly the result of the toxins they produce; therefore, admitting, as we must, the living streptococcus of erysipelas to have a curative action on malignant tumors, theoretically, we have the strongest reason for believing this action to be due to the toxins. The result of practical experience is, as we have seen, in strict accord with theory.

In view of the evidence already presented, is it not more rational to explain the disappearance of these tumors as a result of the specific action of the toxins upon sarcoma, than upon the theory of spontaneous disappearance or of mistaken diagnosis? In regard to these explanations so frequently offered, I would briefly say that after a most careful search of the literature of sarcoma, I have yet to find a single case of spontaneous disappearance in which the diagnosis had been confirmed by microscopic examination. In support of this view I again quote Mr. Bland-Sutton, who, in the discussion of Grieg Smith's well-known paper upon "so-called disappearance of abdominal tumors,"³ stated that he did not believe in the spontaneous disappearance of any connective tissue or cancerous growth, and the spontaneous disappearance of myomata which had been reported was based on clinical observation alone.

In the discussion of my last paper before the Johns Hopkins Medical Society, April 6, 1896,⁴ Prof. William Welch said: "I see no way of gainsaying the evidence which Dr. Coley has brought forward, that there is something specifically and genuinely curative in this method of treatment. A single undoubted cure of a demonstrated cancer or sarcoma by this treatment would be enough to say definitely that the treatment exerts some specifically curative influence, for the spontaneous disappearance of undoubtedly malignant growths of this character is almost unknown. Dr. Coley has, however, presented us positive proof not only of one, but of numerous cases of malignant tumor cured by his method."

As I have already stated in a previous paper, it would be somewhat remarkable that these cases should be the first and, thus far, the only ones with both clinical and microscopic diagnosis of malignancy, to disappear spontaneously; and it would be more remarkable still that this disappearance should be coincident with the beginning of the treatment with the toxins. Furthermore, it would be clearly unfair to rule out these cases on the ground of errors in diagnosis without ruling out the cases of cures following operations for sarcoma. Both have been subjected to the same standard of diagnosis, with this important difference, that the cases treated with the toxins have been subjected to *far more severe tests*, inasmuch as in most cases the clinical and microscopic diagnosis were confirmed by a number of the best surgeons and pathologists.

I admit, there is difficulty in always being able to differentiate between a tubercular or syphilitic tumor and sarcoma, but this applies only to round-celled sarcoma and not at all to the spindle-celled variety which, as Dr. Welch has pointed out, must be classed as a genuinely malignant tumor. If the successful cases were confined entirely to the round-celled variety of sarcoma, there might be some little weight to the argument, but inasmuch as the majority of the successful cases have been spindle-celled sarcoma, a type of tumor in which error of diagnosis is practically impossible, the tubercular or specific theory falls to the ground.

I may possibly be asked to explain the unfavorable report upon the value of the toxins of the Committee of the New York Surgical Society in April, 1896, which has been widely quoted, and which, coming from such a distinguished source, could not fail to raise doubt even in the minds of those hitherto disposed to give the method a fair and unprejudiced trial. Up to the present moment, I have made no attempt to answer this report, save by the presentation before the Society of additional cases successfully treated by the toxins. Since this report was submitted, I have exhibited before this Society four cases of inoperable sarcoma—the diagnosis of which had been confirmed in every instance by the highest authorities in pathology—successfully treated by the method in question. The tumors had entirely disappeared, and one of these cases, a spindle-celled sarcoma of the chest wall and axilla, is now free from recurrence nearly three years, the diagnosis in this case having been confirmed by Prof. Wm. Welch of Johns Hopkins University. I have acted on the principle laid down by Oliver Wendell Holmes more than half a century ago: "It is by notes of cases rather than by notes of admiration that we must be guided when we study the revised statutes of nature." And it is by virtue of these by notes of cases that I appeal from the verdict of the Committee of the Surgical Society.

The simple truth is what I have been seeking, and all honest criticism, so far as it tends to aid in arriving at truth, is most welcome. It is Huxley who says to the young investigator, "*Veritas praevaleret* some day, and even if she does not prevail in his time, he himself will be all the better and wiser for having tried to help her; and let him recollect that such great reward is full payment for all his labor and his pains."

CONCLUSIONS.

A careful study of my own cases, as well as those

³ Brit. Med. Jour., Dec. 10, 1894.

⁴ Johns Hopkins Bulletin, September, 1895.

thus far treated by other men, justifies, I believe, the following conclusions, which, I may add, are in almost perfect accord with those recently expressed by M. Moullin.

1. A considerable number of cases of inoperable sarcomata, the correctness of the diagnosis of which is beyond question, have entirely disappeared under this method of treatment.

2. A large proportion of these cases have remained free from recurrence more than three years after treatment, the period which has generally been accepted as of sufficient length to justify their being regarded as permanent cures.

3. The different varieties of sarcoma differ widely as regards the manner in which they are acted upon by the toxins. The results thus far show that the treatment is far more successful in the spindle-celled variety, more than half of the cases of spindle-celled sarcoma in which the injections were made having disappeared. Round-celled sarcomata yield far less readily, although a number have been successfully treated. No case of melanotic sarcoma has up to the present time shown more than slight temporary improvement.

4. The action of the toxins upon sarcomata must be regarded as a very rapidly progressing coagulation necrosis with fatty degeneration. This action is not the result of inflammation, nor does it resemble the destructive action of a local escharotic like carbolic acid, but it is rather specific in character, exerting a direct influence upon the tumor cells.

5. The specific action is further confirmed by the fact that several cases have entirely disappeared when the injections were made subcutaneously, remote from the tumor.

6. This method of treatment is attended with a certain amount of risk unless certain precautions be taken. The chief dangers to be guarded against are: *a*, collapse from too large doses of the toxins; *b*, pyemia from insufficient care as regards asepsis, especially in cases where there is a granulating or sloughing surface. To prove that the risks are small I may add that in more than two hundred cases treated personally, death was caused by the injections in but two, and one of these cases was so nearly moribund that no treatment should have been begun.

7. The use of the toxins after primary operation as a prophylactic against subsequent recurrence has much to recommend it. If used in such cases, mild doses should be sufficient, and if proper precaution is observed the treatment should be free from risk.

[I wish to take this opportunity of publicly acknowledging my great indebtedness to Dr. B. H. Buxton of the Loomis Laboratory, without whose skillful labors and untiring zeal these results would have been impossible.]

DISCUSSION.

Dr. McARTHUR of Chicago—Since Dr. Coley first introduced this treatment I have had six cases under careful observation and treatment, and last Christmas day I received a very handsome gift from a man who for two years has been free from any recurrence as a result of this treatment. One must bear in mind that the author only recommends his method in cases that are inoperable, and if he saves only twelve cases the attention of the surgical world should be directed to that remedy in the treatment of conditions for which we have no other recourse. I remember the case of a patient who twice refused to have an extremity amputated, although the diagnosis showed plainly it was sarcoma, and he subsequently recovered. One of my cases was a round-celled sarcoma, and the other a spindle-celled sarcoma, and under the treatment by the toxins

the growths disappeared, and the patients are living and well at the end of three years. I believe this method to be almost useless in cases of melanotic sarcoma, but in spindle-celled sarcoma there are very decided reasons for giving it a trial before removing the extremity.

Dr. HARRIS—I would like to ask why the author does not recommend toxins in carcinoma. I have a case under observation where I have been hesitating for several weeks as to what to do in order to obtain information on the subject, and I would like him to tell us why he considers it unwise to use the remedy in carcinoma.

Dr. LEWIS of Topeka—I am very much pleased with the method, especially as I had such a radical cure in one case, which occurred at the angle of the jaw on the right side in a patient of mine two years ago. Seeing that I knew what the result of an operation for such a condition would be, I advised the lady to go to Chicago and have it done there, which she did. Paralysis resulted, as I expected, and I later removed some more of the jaw. Suppuration went on, and eventually the clavicle became involved, and later the tibia, necessitating removal of sections of these bones. Some time afterward she accidentally acquired erysipelas in the face, which healed completely. This stimulated me to use Coley's mixture, and the woman is now well.

Dr. A. D. BEVAN of Chicago—I would like to relate my experience in this connection, as it may throw some light upon the action of the toxins in sarcoma, or in pathologic conditions with which it may be confounded. Within the past year a case of a large gumma of the thigh came under my observation, which was diagnosed at that time as sarcoma, and radical operation was recommended. The patient was loth to submit himself to such radical treatment, and I began the use of the erysipelas toxin. The result was some diminution in the size of the growth, but not to the extent of entire disappearance. I later did an exploratory operation, and removed a section of the tissue, which showed on gross appearance evidence of gumma, and histologic examination confirmed this. He was put upon iodid of potash, and the growth entirely disappeared. He then admitted having had a specific lesion some years before. The idea has occurred to me that possibly, in view of the fact, together with the unanimous opinion of continental surgeons, as well as many of our own countrymen, that in pure sarcoma no results have been obtained by the erysipelas toxin, it may be possible that many of these cases were gumma, resembling sarcoma very closely, which could only be proven by continuous specific treatment.

Dr. COLEY, in closing—I have treated nine cases of melanotic sarcoma, but in no case did I get more than a brief improvement. Up to the present time the results have not been sufficiently good in carcinoma to warrant me in continuing the use of the toxins. The only evidence I have as to the permanency of the cure in these cases is in a case of epithelioma of the mouth. The surgeon had recommended entire removal. The toxins were employed, and the case remained well for three years. As to Dr. Bevan's point, round-celled sarcoma is the only one that could be confounded with gumma. In the opinion of Dr. Welch spindle-celled sarcoma can not be confounded with anything else. As 50 per cent. of the spindle-celled sarcomae have disappeared, which before were hopelessly inoperable, I think the question of mistaken diagnosis is one that can not be entertained.

A SURGICAL TREATMENT FOR HYPERTROPHIED PROSTATE AND HERNIA IN OLD MEN, WITH A REPORT OF TWENTY-EIGHT CASES.

Presented to the Section on Surgery and Anatomy at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY GEORGE W. JOHNSON, B.Sc., M.D.

CHICAGO, ILL.

Concluded from page 400.

Reginald Harrison, F.R.C.S., reports twelve cases of single vasectomy. Seven derived permanent benefit; in the other five, the results were either negative, or it was impossible to trace the patients subsequently. The two cases he reports are as follows:

Case 1.—Patient, aged 69: his prostate was very large. Prominent symptom was extreme frequency of micturition. No catheter used. Amount of residual urine about an ounce, but for some time the patient urinated about every hour, day

and night. Operation was performed with successful result. When the patient was examined five months later, the right testis was found to be atrophied and soft, the left somewhat larger than before. The right side of the prostate underwent shrinkage and was smaller than the opposite lobe.

Case 2.—Patient, aged 72; complained of great frequency of micturition of ten years' duration, eventually amounting to about every two hours, day and night, sometimes oftener. Only a small amount of residual urine, and not dependent on the catheter. The right vas was divided. Six months after the operation micturition was normal in every respect, and although only one vas was divided, considerable shrinkage of the prostate had taken place.

Harrison states that in the majority of his cases micturition became much less frequent after the operation. But in two of his cases operated upon, no benefit was obtained in this respect, and no change was observed in the opposite testicle indicative of hypertrophic activity, and he was not disposed to repeat the operation on the other side. Harrison also reports ten cases of double vasectomy, for five of which he claims great, and believes lasting, benefit. Of the remaining five two have derived but very little benefit; two he was able to trace, and one, rather unusual, he reports as follows:

Patient about 70. In addition to suprapubic fistula consequent upon lithotomy, he had a very large, hard and fibrous prostate. The size of the latter was diminished by dividing the vasa. Two months elapsed between the first and second division. The result occasioned the abandonment of the catheter previously used constantly. Prostate half the size. Fistula also reduced to its smallest dimensions. Although only one and a half inch of each vas was removed, yet the patient retains the necessary desire and power for sexual intercourse. (*British Medical Journal*, 1895, Vol. ii, p. 993.)

Macewen reports three cases in which the prostate was atrophied by bilateral castration.

Case 1.—Aged 64. Feeble and frequent micturition for seven years; required to use the catheter frequently for attacks of retention. Passed urine every one and a half or two hours with much pain; length of urethra nine and a half inches; prostate much enlarged toward rectum, soft and elastic. Residual urine four ounces; urine alkaline and contains a considerable quantity of pus.

Double orchidectomy. Testicles of normal appearance and spermatozoa present. Wound healed without suppuration. In a week patient felt greatly relieved; could retain urine three or four hours. In a month prostate as felt per rectum sensibly smaller; urinated every four hours; quantity of pus diminished. At the end of two months the prostate was less than half its size at the time of operation. Patient passing urine three times a day and once or twice by night. Urine showed only mucous deposit; length of urethra eight and three quarter inches.

Case 2.—Aged 84. Symptoms began with complete retention, when urine had to be drawn off. Entirely dependent on catheter; expulsive power of bladder feeble; length of urethra ten and one-half inches. Prostate as felt per rectum much enlarged, hard and flattened.

Double orchidectomy. Microscopic examination showed testicles in a state of involution. Spermatozoa absent. Two weeks later no difficulty with catheter. Size of prostate unchanged. Two months after operation required catheter once in twenty-four hours. The remainder of the urine passed voluntarily. Length of urethra nine and one-half inches; urine clearer, deposit mucus and a few pus cells. Prostate diminished by one-half.

Case 3.—Aged 71. Had urinary difficulty for ten years, seven of which patient was compelled to depend upon the use of the catheter. Difficulty in passing urine with occasional discharge of blood. Before the operation he was obliged to use the catheter every two hours. Length of urethra ten and three-quarter inches. By the rectum prostate was found to be very large and somewhat hard.

Double orchidectomy. Testicles normal; no spermatozoa found. Catheter used without difficulty every four or five hours. Size of prostate per rectum unchanged. Three months after operation use of catheter required every six or seven hours. Length of urethra ten and one-half inches. Per rectum no appreciable change in size of prostate. (*Brit. Med. Journ.*, 1896, Vol. ii, p. 989.)

Colclough reports a case of double vasectomy; death; partial necropsy. Man aged 70 years, of unusual physique and heavy whisky drinker. At the age of 67 prostatic trouble commenced. Irritability of the bladder gradually commenced with attacks every three or four months. The patient then suffered from an attack of acute cystitis; the prostate was enlarged, but with "catheter life" the patient was comfortable, and not until fourteen months later did urethritis commence. The left lobe of the prostate increased considerably; the urethritis became almost constant. Examination of the left epididymis showed chronic enlargement. Vasectomy was performed. Patient survived the operation five weeks. Postmortem showed the prostate gland a simple bag of pus; the bladder was anchored down to the posterior wall of the abdomen; the left kidney bound down by adhesions and felt like a bag of fluid. The right kidney was hypertrophied. The lateral lobes of the prostate oozed with pus; the middle lobe was soft and pendulous. The lower two-thirds of the bladder was sacculated and thickened, with pus in all the sacculations. The right ureter opened normally, while the left was embedded in a mass of new growth. Below this mass was a closed-in abscess cavity with smooth walls. (*London Lancet*, 1897, Vol. ii, p. 658.)

Cabot reports a case in a strong man of 75; troubled five years with difficulty in urinating. He suffered from an attack of acute inflammation of the bladder. Catheter was used regularly. Castration was performed. After the operation patient's mental condition changed decidedly; he became maniacal. Injection of testiculin was tried with successful result, after which patient's mental condition was greatly improved. The prostate was the size of a hen's egg. Third lobe enlarged to the size of a pullet's egg and projected upward and backward into the bladder. On its apex there was a calcareous deposit firmly adherent. Posterior to this, extending forward in the body of the prostate was a cavity with smooth walls, which contained about a teaspoonful of gravel. Bladder wall was thickened and injected, and showed on its surface a few hemorrhagic spots. Kidneys were in a state of acute pyelonephritis, and the right was about one-third larger than normal. (*Annals of Surgery*, 1896, Vol. xxiv, p. 265.)

Morton, F.R.C.S., reports a case of prostatic hypertrophy in which he performed bilateral castration. The patient was 70 years old, with prostate moderately enlarged, hard, nodular, and there were twelve ounces of residual urine. Owing to the catheter not being kept clean, septic cystitis occurred. Both testicles were removed by a small median incision. There was no mental disturbance following. Very gradual atrophy of the prostate took place. A year later, when examined, it was normal in size, but patient still had the same amount of residual urine, although micturition was easier. There was a little pus in the urine which flowed through the catheter just before the bladder became empty. (*Brit. Med. Journ.*, 1896, Vol. ii, p. 995.)

C. Mansell Moullin reports two cases in which castration was performed for enlargement of the prostate.

Case 1.—Aged 74. Prostatic disease advanced. Perustomed the prostate was of enormous size. Patient was accustomed to use of catheter for many years. The urine, in spite of the bladder being regularly washed out, was foul, ammoniacal and loaded with mucus and phosphates. Bladder was so contracted from cystitis of several years' duration that it held only two ounces of urine. Patient wore portable urinal during daytime,

and in spite of morphia suppositories passed urine fourteen or fifteen times at night. Castration was performed. Three days later patient was able to dispense with morphia for two nights; slept an hour and a half at a time, the longest spell previously being three-quarters of an hour. Ten days later, as per rectum, prostate was found much smaller; stream of urine larger; urine was neutral in reaction, and small masses of phosphates were beginning to come away. One month after operation the prostate diminished so much that a metal catheter with ordinary curve passed without difficulty. Size of bladder increased a little; it retained at times four ounces of urine, but micturition was frequent day and night. No morphia was required. The patient frequently slept two hours without being disturbed.

Case 2.—Aged 64. Prostate very large; repeated attacks of cystitis and several attacks of profuse hematuria. Catheter was passed every hour, night and day. Castration was performed. There was no shock, and patient rallied well. Wounds healed. A small quantity of urine passed naturally, the first time in fifteen months. Eight days after the patient had a fainting fit, urine drawn off by catheter, and contained a good deal of blood. Two days later dyspnea and hematuria returned; diarrhea set in, the bowels acting eleven times in twenty-four hours. Death occurred on the eleventh day after operation. Two days previously blood-stained urine was passed at intervals by the urethra. Heart failure was the cause of death. (*Clinical Society Transactions*, Vol. xxviii, p. 193.)

Griffiths reports a case of enlarged prostate in which bilateral or complete castration was performed. The patient was 74 years of age and had severe cystitis of long duration. Urine contained a large amount of mucus and pus. Micturition was frequent and painful. Catheter was used for two years. Prostate per rectum as large as a medium-sized orange. Castration was performed. Testicles were of full size, and in the left there was a large spermatocele. In each testicle there were active spermatozoa in the seminal tubes. One week after the operation a few ounces of urine were passed without the aid of a catheter. Urine still contained pus, and the patient complained of much pain in the loins. At the end of the second week patient suffered from sleeplessness, becoming delirious. On the fourteenth day after operation the right popliteal artery became blocked, the limb below showed signs of beginning gangrene. Eighteen days after the operation the patient died.

Postmortem: The right kidney was found enlarged from chronic hydronephrosis; suppuration of the distended pelvis; left kidney natural. The bladder was thickened, mucous membrane and right ureter much inflamed. In the right popliteal artery, a mottled and adherent recent clot. The prostate still enlarged, etc. (*Brit. Med. Journ.*, 1895, Vol. i, p. 579.)

Fenwick reports nine cases of double castration (White's operation) upon the enlarged prostate. He considers White's method for the shrinkage of enlarged senile prostate an important addition to our present methods. The reports of cases are as follows:

Case 1.—Test case for shrinkage of the normal human prostate after castration. Entire genitals of a man, aged 45, ablated by the Thiersch-Gould method for extensive epithelioma of the penis. After six months the prostate was reduced to the size of a small bean.

Case 2.—Aged 76. Some years of feeble prostatic micturition. Sudden and prolonged retention. Extreme difficulty of catheterization. Prostate unusually hard and enlarged, especially in the left lobe. Double castration. Three weeks after urine passed voluntarily without the use of catheter. Suprapubic wound closed. Prostate much diminished.

Case 3.—Aged 70. Symptoms of enlarged prostate for six years. Attacks of retention. Slight cysto-prostatitis with mild pyelitis present; inflammatory conditions commencing a year before castration. Per rectum, the prostate was small, but the lateral lobes were much upraised toward the bladder, the vas at the vesical orifice being edematous and translucent. Bladder was fasciculated and pouched. First week after operation the urine cleared, stream improved in force and the pain on urinating diminished. At the end of the third week the prostate was a little smaller, structures of the lobes more fibrous,

and the interlobar line had filled up. After three months the stream had markedly improved in force, and only slight variability in power of bladder remained.

Case 4.—Aged 76. Repeated attacks of retention and uremia. Catheterization most difficult. Prostate plump and elastic, only moderately enlarged per rectum. Suprapubic drainage for months without improving the cystitis. Double castration. Cystitis rapidly diminished and voluntary micturition recovered after a fortnight. Prostate slightly smaller at the end of the third week.

Case 5.—Aged 76. Dysuria for five years; not much relieved by catheter, which was passed almost every hour. Irrigation of the bladder had no control over the cystitis. Double castration. Prostate slowly diminished in size. Catheterization only needed every six hours. Cystitis diminished.

Case 6.—Aged 81. Catheter used for nine years, six or seven times during the night and three times during the day. Efforts to pass the instrument were often followed by hemorrhage. Prostate per rectum large and elastic, especially the left lobe. Castration performed. For three days after operation catheter needed twice in twenty-four hours, then four times. At the end of three weeks the prostate diminished and interlobar line of demarcation had filled in; cystitis greatly decreased, but catheter had to be used three times at night.

Case 7.—Aged 60. Dysuria for about three years, with occasional use of catheter, followed by cysto-prostatitis. Prostatic abscess formed and burst into the urethra. Intense pain after every feeble attempt at urination, finally retention. Catheterization for a week. Prostate enlarged laterally and elastic. Castration. Recovery of voluntary micturition on third day; slight shrinkage of the prostate after two weeks. Prostate plump and elastic, diminished one-eighth by the fourth week.

Case 8.—Aged 46. Aggravated prostatitis with great local pain, tenderness, severe and intractable neuralgic radiations for ten years; also increased frequency of micturition. Sitting or walking unbearable. Castration. Prostate slightly smaller; as yet no marked relief. Final condition to be reported later.

Case 9.—In progress.

The above cases were in urgent need of relief and were selected from a large series of prostatics for the operation. It will be noticed that they illustrate the use of the operation in four groups of cases: 1, those cases in which castration was performed early, that is, before the vesical muscle had been permanently crippled, but not before it had been impaired; 2, those in which the muscle power had been abrogated by years of catheterization, and in which death was approaching from ascending pyelitis; 3, those in which the ordinary obstructive symptoms were aggravated by chronic inflammatory troubles of the senile prostate; 4, one mid-adult case of incurable chronic prostatitis and vesiculitis which was complicated by unrelievable neuralgic radiations. (*Brit. Med. Journ.*, 1895, Vol. i, p. 378.)

Hayden reports a case of hypertrophy of the prostate gland in which double castration was performed. Patient aged 70. For five years had frequent urination day and night; use of catheter painful and difficult. Straining caused protrusion of several hemorrhoidal masses. Urine ammoniacal. Bladder holds six ounces of fluid; severe cystitis. Prostate twice its normal size. Double castration performed. Twenty-four hours after operation there was a severe spasm of the compressor urethrae muscle, necessitating use of catheter. There was also spasm of the anal sphincter. Fifth day after, much improved. Catheter passed to the bladder. Two months later patient was absolutely free from all pain. Prostate per rectum a little enlarged, but non-painful. (*Medical Record*, 1895, Vol. xlvii, p. 612.)

Lilienthal reports a case of enlarged prostate practically cured by castration. Patient, aged 56. For ten years was troubled with frequent micturition; occasional attacks of vesical tenesmus. Catheterized for retention. His urine was alkaline, and there was severe cystitis. The urine contained quantities of

pus and bloody mucus. Prostate per rectum found to be enlarged three times its normal size. Both testicles were removed; signs of slight bilateral epididymitis. First improvement noted was that the patient could pass a stream: cystitis vanished. Four weeks after the use of the catheter was not necessary. Per rectum prostate still enlarged, but only half the size it was before, and feels flaccid. (*Medical Record*, 1895, Vol. xlvii, p. 506.)

Rand reports two cases of hypertrophied prostate relieved by castration.

Case 1.—Aged 58. For ten years patient had more or less difficulty in urinating. Five and a half ounces of residual urine were present at first catheterization. Both testicles were removed. Second day after operation he voided twelve ounces of urine voluntarily at different times during the day. Five weeks after, residual urine, off and on, was absent, or in small quantity. Prostate per rectum much smaller, and a small-sized sound drops into the bladder by its own weight.

Case 2.—Aged 69. For nine years patient has had frequent urination. Length of urethra eight inches. Residual urine six or seven ounces at times. Prostate twice its normal size. Both testicles removed. No shock nor pain followed. The size of prostate decreased rapidly within eleven days after operation. (*Annals of Surgery*, 1895, Vol. xxii, p. 217.)

Bryson reports a case of prostatic overgrowth relieved by complete castration. Patient, aged 74. At 56 he gave first evidence of prostatitis. There was dilatation of bladder from obstructive prostatic overgrowth. A cystitis and mild pyelonephritis also developed. Dilatation of heart and pulmonary emphysema supervened. Demonstrable results followed the operation. There was a marked diminution of the enlarged prostate without any change in frequency of urination, without alteration in the amount of tidal urine, and with but slight decrease in the amount of residual urine. In short, complete castration caused complete atrophy of prostatic gland without effecting any change in the chronically inflamed and degenerated bladder, and equally without curing or benefiting a chronic pyelonephritis from extension. (*Journal of Cutaneous and Urinary Diseases*, 1895, Vol. xiii, p. 352.)

Chetwood reports two cases of prostatic hypertrophy after operation: one by vasectomy; the other by castration.

Case 1.—Aged 52. Patient had never had treatment for bladder until his first attack of retention of urine, and catheter was passed for the first time. Prior to this he had frequent urination night and day. About eight months later he was operated on for fissure of the rectum; bladder trouble aggravated after operation, and he was regularly catheterized. Third day after, introduction of catheter was difficult, followed by hemorrhage. Patient was examined ten days later, and per rectum enlarged prostate was found, it being the size of a hen's egg. Third lobe prominent. An incision was made over the external ring, and after separating the vas deferens two ligatures were applied and one-quarter inch of the canal between them was resected. For ten days a record was kept of the amount of urine passed per catheter and voluntarily. At first the amount of urine passed by catheter greatly exceeded that passed voluntarily, but toward the end of the week the amount was reversed, so that at the end of the ten days the patient was able to empty his bladder down to about four ounces. The patient became lax in the proper care of himself and his old trouble returned with increased activity. Frequency and urgency of urination became aggravating and attacks of retention more frequent than before. About one year after operation his condition was worse than the previous year. Prostate was the same size and larger. Dr. Chetwood remarks that he is forced to believe that whatever relief he experienced was due to his introduction into catheter life. He says he finds that cases of vasectomy reported by Guion, Cartier, Helferich, Legen, Isnardi, and others, in most of which conclusions reached seemed decidedly negative, while in some instances there seems to be a certain amount of functional improvement with one exception, that there was no decided diminution in

the size of the prostate, and it is a question when improvement was noted whether or not it was due to the operation.

Case 2.—Patient, aged 81. Difficulty with urinary function for ten years; several attacks of retention which were relieved by catheter. For four years catheter passed twice in twenty-four hours. Examination showed four to six ounces of residual urine; penile distance nine inches; prostate fibrous and hard, upper distance barely touched with end of index finger, distance being about three and a half inches from below upward, and about three inches laterally. Double castration performed. Recovery from operation uneventful. During the two weeks following relaxation of regular catheterization and bladder irrigation there were symptoms of bladder irritability, turbidity of urine and tenesmus. Prostate was reduced one-third in size and softer in consistency; residual urine was reduced one-third; penile distance half an inch shorter. Five weeks after, urine flowed freely, and catheter not required. Urine, however, quite turbid. Two months after operation the bladder was irrigated at regular intervals; urine passed once every two hours by day; catheter used before retiring at night, by which means patient slept without again rising. Examination reveals that the prostate was reduced one-half its original size, and penile distance from three-fourths to one inch less than length before operation.

Regarding the subject of double castration from various cases reported in the journals of Guion of Paris and Casper of Berlin, Dr. Chetwood thinks that there is little doubt that removal of the testicle produces a certain amount of shrinkage in the prostate gland, but with a varying amount of subsidence of the functional disturbances. He doubts if the operation ever will be popular. (*Journal of Cutaneous and Genito-Urinary Diseases*, 1897, Vol. xv, p. 111.)

Howitz reports four cases of stone in the bladder with hypertrophy of the prostate gland, where a positive diagnosis was impracticable until double castration resulted in atrophy of the prostate, rendering the passage of a stone searcher possible.

Case 1.—Patient aged 70 years; suffering from symptoms of cystic stone, which were intensified for five years; urine contained blood. Per rectum hypertrophied prostate; no stone searcher could be passed. Double castration was performed. Two weeks after operation a stone searcher was readily passed and the existence of calculi easily detected. These were removed by a suprapubic cystotomy and patient recovered rapidly.

Case 2.—Aged 65 years. History of case similar to Case 1. Obstruction produced by enlargement of prostate, permitting passage of small catheter only. Double castration was performed. Fourteen days after a stone searcher was readily introduced and a large-sized calculus found, which was removed by a suprapubic cystotomy. Patient also recovered rapidly.

Case 3.—Aged 62 years; hypertrophied prostate. In addition to the usual symptoms there was great pain in the glans penis, especially after urination. Patient frequently passed blood before and after micturition; two attacks of retention of urine. Double castration preliminary to cystotomy. Ten days after operation stone searcher readily passed; two good sized calculi were found in a pocket posterior to the prostate and were removed by a suprapubic operation. Patient entirely relieved.

Case 4.—Aged 71 years. Pain in the head of penis, neck of bladder and over pubes after passing water. Frequent attacks of hematuria; one attack of ischuria. Prostate much enlarged. Double castration performed. Fifteen days after prostate sufficiently shrivelled to allow the introduction of stone searcher, when a calculus was located. It was small and easily crushed. Patient made a slow but complete recovery. (*Therapeutic Gazette*, 1898, p. 73.)

Watson reports three cases of castration for the relief of prostatic hypertrophy.

Case 1.—Aged 58 years. Patient suffered from symptoms of urinary obstruction for several years. Several attacks of retention of urine. After use of catheter symptoms became worse, and before the operation patient had a painful desire to urinate every fifteen minutes day and night. During five days preceding operation he was unable to void urine spontaneously to the extent of an ounce or two in twenty-four hours. Continuous drainage of bladder by a catheter in the urethra was not tried before operating. Both lateral lobes of prostate were markedly hypertrophied, the surface of the right lobe some-

what uneven and in the course of the vas deferens there was a hard, round body the size of a pea, which was movable. Castration was performed through two incisions, one over each testicle. Operation somewhat prolonged by the presence on one side of an encysted hydrocele of the cord, which was dissected out. Immediately after the operation the use of catheter was discontinued. Previous to operation retention followed if catheter was omitted. No change in the frequent or painful desire to urinate. At the end of thirty-six hours, and interval of one hour and a half. On the sixth day patient passed out four ounces of urine at each micturition spontaneously. On the tenth day he was free from pain. Three weeks after operation there was but an ounce and a half of residual urine, which was almost free from pus. Distinct diminution of size of prostate. Patient slept five hours at a time undisturbed. In daytime he is obliged to urinate once in three or four hours. Operation considered a complete success.

Case 2.—Aged 69 years. Both testicles removed through a single median incision. Slight hypertrophy of lateral lobes. The catheter passed nine and a quarter inches before entering the bladder. Symptoms of urinary obstruction for three years; catheter could not be omitted without retention. After operation catheter could not be omitted. The wound did well up to forty-four days after operation; no other improvement noticed; no perceptible change in the size of prostate. So far, case is a failure.

Case 3.—Aged 70 years. Retention of urine. Symptoms of urinary obstruction for several years; overflow of bladder for several months. Patient had double inguinal hernia of long standing. Prostate much enlarged; constant and painful desire to urinate and at times violent bladder tenesmus. During the night following operation patient tore off bandages, got out of bed, and in a violent fit of coughing forced down the hernia, distending the scrotum and putting the wounds on the stretch. Patient died on the ninth day. No spermatozoa were found at the time of operation. Autopsy showed hypertrophy in the form of distinct fibro-adenomatous tumors, each lateral lobe containing a thickened capsule the size of a horse chestnut. No atrophy of the prostate occurred. Vesiculæ seminales contained no spermatozoa. Bladder the seat of chronic cystitis. Extensive pyelonephritis of both kidneys. (*Boston Medical and Surgical Journal*, 1895, p. 378.)

Kümmel reports three cases of successful operations of hypertrophy of the prostate by excision of the middle lobe of the prostate. This is the same method which is employed by McGill, Harrison, Landerer, Benno, M. Schmidt. First the bladder was disinfected and opened under the simultaneous use of Nelaton's catheter and the use of antiseptic solutions. Then the middle lobe of the prostate was caught with a forceps, drawn upward and slowly singed by means of a Paquelin cautery, or a glowing loop, afterward in several parts, working around as in cutting out the roots of a potato. Then a Hegar's dilator was employed, a permanent catheter introduced, and the wound closed by suture. The mucous membrane was sutured separately with catgut. Nelaton's catheter was removed fourteen days later. The three patients were 65, 70 and 72 years old, respectively. The cure was complete. (*Deutsche Med. Woch.*, 1889, pp. 310 and 314.)

Dr. William T. Belfield reports fifteen cases of severe cystitis dependent on prostatic enlargement, confirmed by autopsies, and says that he found intravesical tumors in eight, three times, as a single myoma or middle lobe, and in five as a more or less complete ring around the vesical orifice. In five, the growths were deeply intraprostatic, and in two diffuse hypertrophy with encysted calculi. In eight of the fifteen cases the prostatic obstructions were removable. Dr. Belfield recommends operation by perineal or suprapubic incision.

In cases of prostatic enlargement where the cystitis is still slight he recommends the use of an intense galvanic current, after Apostoli's method with uterine fibroids. (*Medical Record*, 1888, Vol. xxxiii, p. 272.)

Heine reports four cases of successful cure of

hypertrophy of the prostate by parenchymatous injections, consisting of a solution of iodine, with no suppuration after the injections. The solution was kali iodid, 2 drams; tincture of iodine, 2 ounces; and, aqua distil, 6 ounces. Between twelve to twenty drops at a time were used. After a second injection the prostate was considerably diminished in a man of 75 years. Heine claims this as a radical method. In one case the prostate, after the injections, was even smaller than is usual with a healthy man. (Langenbeck's *Archiv für Klin. Chirurgie*, Vol. xvi, pp. 79-95.)

Mayer and Haenal report a case of hypertrophy of the prostate relieved by castration. Patient, aged 70. Prostate much enlarged, with cystitis and ammoniacal urine, tenesmus and toxemia, in whom catheterization was almost impossible on account of the pain produced. Several ounces of residual urine. Several days after operation improvement was noticed. Two weeks later the tonicity of the bladder began to return. In three weeks, urine nearly normal. In six weeks the prostate had shrunk to the proper dimensions and the bladder emptied itself completely, no catheter being required. Patient urinated every four hours; uric acid in reaction. (*Centralblatt für die Krank. der Harn. u. Sexualorgane*, Aug. 25, 1894.)

Helferich reports a case of typical hypertrophy of the prostate in a man of 70 years, which he cured successfully by resection of the middle lobe of the prostate. First, sextio alta, then injection of borate solution into the bladder, then excision of middle part of prostate.

Bottini reports three cases of radical cure resulting from hypertrophy of the prostate. This method is invented by himself and consists in galvano-caustic destruction of the growth. The galvano-cautery for the prostate is in form similar to the Soude angulane Mercier tube. (Langenbeck's *Archiv für Klin. Chir.*, Vol. xxi, p. 1.)

Dr. Landerer's method of treating hypertrophy of the prostate consists in the removal of the middle lobe of the prostate, which is in many cases the only hindrance to urination. This method was found by an attempt to remove a supposed vesical calculus; yet it really cured hypertrophy of the prostate. This method is the same as that employed by Volkmann and Thompson for the removal of tumors of the bladder. The scissors used is a combination of polypi scissors and hollow chisel scissors. (*Deutsche Zeit. für Chir.*, Vol. xxv, pp. 5-11.)

Leisrink reports a case of total extirpation of the prostate in order to remove a prostatic tumor. The prostate was enlarged to the size of an apple, almost closing the lumen recti, the mucous membrane of the rectum and the tumor. The adhesions were separated with the finger and the prostate isolated. The small tumors were removed with Cooper's scissors; the wound dressed with iodoform. The next day the wound was washed with thymol solution. Complete success. (Langenbeck's *Archiv. für Klin. Chir.*, Vol. xxviii, pp. 5-78.)

Ricketts reports a case of enlarged prostate relieved by castration. Patient aged 64. On second day after operation the patient urinated with greater ease and pain was slight. He slept four hours at a time during the night, where formerly he had been obliged to urinate every hour, urinating thirty times daily. Condition continued to improve. (*Cincinnati Lancet-Clinic*, Dec. 1, 1894.)

Fremont Smith reports a case of enlarged prostate in which double castration was performed. Patient was an old man with prostatic hypertrophy and cystitis, general infection and threatened uremia. After operation catheter was used twice daily at first. Twelve weeks later patient reported to Dr. Smith that he had gained forty-five pounds in weight and had no symptoms of cystitis. (*New York Med. Jour.*, 1895, Vol. lxi, p. 585.)

Glück and Zeller have made experiments on living dogs and cadavers for total extirpation of the bladder and prostate. They find that dogs can easily stand extirpation of the bladder and prostate. They also sutured the urethra to the abdominal wall. Dr. Sonnenburg has followed this method on a living man with success. (*Verhandlungen der deutschen Gesellschaft für Chirurgie*, Vol. x, pp. 158-166.)

Kümmel has produced artificial atrophy of the prostate by castration in eight cases, with the desired result.

Wagner of Leipzig reports that under six operated cases, four persons died of acute mania; while under fifty-three other cases from different countries, no such consequences are reported. (*Schmidt's Jahrbuch der gesamten medicin*, 1895, pp. 162-3.)

In the German International Congress of Innerliche Medicin, Dr. Reinert of Rubingen gives a new treatment for prostatic hypertrophy. He reports three cases which were considerably relieved by the ingestion of the preparation of the prostate glands of animals. (*Trans. Deutscher Congress f. innerliche Medicin*, 1895.)

Thomas reports a case in which castration in a patient, 65 years of age, who had had symptoms of prostatic hypertrophy for fifteen years, had caused "considerable improvement." Urination formerly was very frequent, but after operation he was required to urinate only three times a day. (*Pittsburg Medical Review*, September, 1894.)

DISCUSSION.

Dr. G. FRANK LYDSTON of Chicago—Dr. Johnson's paper is one of the fairest presentations of what may be termed the unusual method of treatment for hypertrophied prostate—for it is of that portion of his paper particularly that I will speak—that has thus far been presented. He has eliminated what has seemed to me the principal weakness of the successful cases of orchidectomy and vasectomy thus far reported, namely, the effect of rest in producing diminution in the size of the prostate and improvement in the symptoms secondary to prostatic enlargement. It has been my experience that improvement very rapidly occurs in the majority of cases that are put to bed under proper measures of treatment. There is in all instances a greater or less degree of more or less recent hyperplasia due to irritation; this is a plus condition which rest very rapidly subtracts. In many of the cases that have been reported, considerable improvement has been claimed within a short time after the orchidectomy or vasectomy has been performed. In a large proportion of these the accuracy of the report is open to doubt, because of the fact that the rest incidental to the preparation for and following the operation must necessarily have subtracted to a certain degree the superadded conditions of congestion and recent hyperplasia present in such cases. There is no doubt but that vasectomy, and more particularly orchidectomy, are founded upon logical and philosophic principles. It is unnecessary for me to enter into a discussion of the influence of the testes upon the development of the prostate and seminal vesicles. J. William White has presented this subject so explicitly and fully that there is practically nothing to be added to it. There is no question but that the nutrition of the prostate is controlled or modified to an essential degree by what may be termed the physiologic reflex of the testes. There is also no question but that removal of these organs will produce an alteration in the nutrition of the prostate which, in the normal organ, results in atrophy, and in abnormal conditions of the organ results in shrinkage of the adventitious tissue and benefit or cure of

any abnormal conditions of the bladder which may exist as secondary features of obstruction at the vesical neck. I have found that in the majority of cases there is marked opposition to the operation of castration on the part of patients. Very few patients indeed will consent to the operation until their sufferings become so extreme that they are compelled to submit to obtain relief. Under such circumstances they are willing to submit to almost anything that promises them relief.

The sentimental and cosmetic objections advanced, even by patients who have long since been deprived of the function of the testes, are so strong that the range of cases to which the operation can be applied is considerably narrowed. On this account vasectomy, which, although not as efficacious as castration, is beneficial or curative in a fair proportion of cases, may often be performed where castration would be refused. I believe that castration has too frequently been performed in cases which were by no means suitable to the operation. One thing is certain, that in the presence of a fair condition of the kidneys, no man, whose sexual function has not disappeared, should be submitted to castration. No matter how severe the local symptoms may be, it would be far better to submit the patient to the radical operation of prostaticotomy or prostatectomy, or even to perform palliative suprapubic cystostomy and the formation of a permanent suprapubic fistula, than to run the slightest risk of performing an operation for which the patient would not only reproach himself, but what is much more to the point, as far as the reputation of surgery in general is concerned, reproach us. Personally, I am in favor of radical operations upon the prostate itself, performed at an early period, when the operation is not only safe but offers an excellent prospect of radical cure. The trouble has been in the case of prostaticotomy and prostatectomy, that these operative measures have only been resorted to in desperate cases. The general practitioner has been led to believe that no operative measures are warrantable in hypertrophy of the prostate, and so we have gone on and on in neglecting our cases until the last moment, when the old man has been operated upon simply because he was going to die anyhow, and then we marvel at the non-success of radical operations upon the prostate. I unhesitatingly affirm my belief that the statistics of operations upon the prostate thus far obtainable are well-nigh valueless, so far as showing the results of cases operated on under proper conditions is concerned.

I agree with Dr. Johnson in his statement that a digital examination per rectum should be made in every case where there is a suspicion of prostatic disease. He is correct in his assertion that palliative treatment often cures supposedly grave cases of prostatic disease. In many instances the condition of enlargement of the prostate is one simply of hyperplasia and congestion which lasts for many years before fibroid degeneration or adenomatous change occurs. Under these circumstances massage of the prostate and measures calculated to relieve irritation of the vesical neck, which is very often responsible primarily for the hyperplasia of the prostate, are frequently curative.

I can only compliment the doctor upon the careful manner in which he has operated upon and studied his cases. His favorable results, in my opinion, in what are certainly serious operations upon old men, are due in great measure to the care with which he prepares the patient for operation. I believe that Dr. Johnson is correct in attributing the mental symptoms that appeared in three of his cases to renal disease. I do not like the expression, however, "due to the presence of albumin in the urine." The albumin has nothing to do with it. In such cases it is the insufficiency of the kidney, as far as the elimination is concerned, that is responsible for the brain symptoms, and these brain symptoms, by the way, are by no means infrequent with operations upon the bladder and prostate, or indeed any operation for the relief of chronic genito-urinary disease. I have in mind at the present moment the case of a gentleman who was insane for five months with suppression of urine, coming on four weeks subsequent to a successful perineal section for the relief of deep stricture. The gentleman eventually recovered completely.

The hernia operations performed in the class of patients coming under Dr. Johnson's care were certainly followed by very remarkable results, and are very encouraging with respect to the radical cure of hernia, especially when we consider the extreme age of the patients operated upon.

In conclusion, I will state that I am especially pleased with the cases reported by the author because of the fairness with which he has presented them. Such cases are reliable data from which to work in determining the advisability and value of castration and vasectomy for prostatic disease. There is no doubt but that these operations have a brilliant future before them. The principal objection I have to them is that they are

liable to interfere with the progress of radical operations upon the prostate, which, if performed early in life, will obviate long years of suffering, and will bring about a radical cure in cases that eventually would be compelled to submit either to radical operations upon the prostate at a time when the results would be extremely doubtful, or to castration. It must be remembered, that there is a large number of cases in which the patient suffers fearfully from prostatic disease: yet the sexual function remains practically unimpaired, and castration is not to be thought of for a moment. Such cases as these in my opinion will always constitute a demand for earlier and improved operations upon the prostate proper.

Dr. J. B. MURPHY of Chicago.—I desire to compliment Dr. Johnson on his excellent paper, and more particularly to congratulate him, first, on the line of investigation he has chosen; and, second, on the success he has attained in this unpromising and neglected field of surgery. The general practitioner, and, indeed, the general surgeon, are too prone to say to the unfortunate victims of prostatic disease, "Your trouble is one of the diseases of old age, and little, if anything, can be done for you." The poor old man is thus doomed to continue suffering such pain, such agony, such nocturnal disturbance, in short, such torture, that all things of the world, including life, are of negative value to him.

I feel that Dr. Johnson deserves the thanks of the Association for presenting this subject in such a terse and forcible manner. The emphasis placed on the careful examination should be reiterated, and particularly the careful sounding of the bladder for post-prostatic calculi, and the combined recto-digital and sound examination for intra-prostatic calculi. These are many times overlooked, and produce the most painful conditions of the prostate. To prevent the "catheter life" of the aged is worthy our best efforts, and Dr. Johnson has succeeded admirably. The cure of the hernia was of great value to the patients, and the results as far as life is concerned encourage the daily practice of this operation. It pleases me that so much stress was placed on the rapidity of operation, as I am sure the element of time was a most important factor in securing success in the old and degenerated subjects I saw in his Infirmary. Another good point made by the essayist is the avoidance of incision or manipulation of the scrotal tissue. This tissue is very prone to infection if lacerated or exposed. The improvement of the vesical symptoms took place slowly in most of Dr. Johnson's cases. This corresponds with the course of my cases, as I have seen none of the instantaneous cures supposed to follow this operation. I am in favor of orchidectomy for prostatic disease. I had an opportunity of observing some of the author's work and to see many of his cases after operation. His results were very gratifying.

Dr. OCHSNER of Chicago.—Six months ago, at a meeting of the Mississippi Valley Medical Association, I drew the attention of the surgical section of that body to the fact that in old men hernia frequently became exceedingly troublesome, which had formerly usually been supported by means of trusses. This I considered to be due to the increase of intra-abdominal pressure, which was necessary to evacuate the bladder on account of the obstruction caused by the enlargement of the prostate gland. Having had an opportunity to observe many cases, and having had charge of five, in all of whom I relieved the condition by means of the operation which Dr. Johnson has described, and in all of which the result was extremely satisfactory—the patients being at once relieved of the difficulty resulting from the presence of the hernia and from the obstruction—has caused me to recommend this procedure. I am gratified to know that Dr. Johnson has made use of the extraordinary opportunity at his command in having care of such an enormous number of these cases, and I am equally gratified to learn of the excellent results. In children, we have a condition somewhat similar, and hernia are very much more common in male than in female children, although I do not remember the proportion. This difference is largely due to the fact that the male children suffer from phimosis. In a very large number of children I have cured the condition by simply operating to relieve the phimosis, keeping them in bed with their hips elevated for a few weeks thereafter. This method cures, practically, all cases of male children suffering from hernia. The fact, however, that hernia occurs in Jewish children does not alter the question, as these boys will also be cured if treated in the way I mention. We have here a condition which is very similar, and I think it is worthy of consideration. I have performed the operation a number of times with equally good results.

Dr. ALEXANDER HUGH FERGUSON of Chicago.—The operation for the radical cure of hernia in addition to removal of the vas deferens and castration being an additional danger to these cases, points out the comparatively safe manner with which

gonangeiectomy and orchidectomy may be performed. It also supports the theory of the ability of old people to withstand operations. It has been my good fortune to see most of the cases reported here today by Dr. Johnson, and although I have not made a critical examination of them, I learned from themselves that they were completely relieved of their former bladder trouble, or were vastly improved. I can also bear testimony to the careful aseptic surgical work done by Dr. Johnson at Dunning. Being a visiting surgeon to that institution myself, he has assisted me in a large number of operations on the aged poor.

It is not necessary on this occasion to say anything about the different methods for radical cure of hernia. Ever since Dr. White of Philadelphia, in 1893, brought this treatment prominently before the profession, for hypertrophied and enlarged prostate, several hundred cases have been treated in this manner, and even the most conservative surgeon must admit that the treatment is beneficial in a large percentage of these cases. Dr. Johnson has been fortunate in the selection of his cases, and the results he has given us today are exceedingly happy. It must not be taken for granted, however, that all prostatiques will behave so well and so completely recover after either of these operations. You may call it empirical surgery, if you please, but the good results obtained in cases that have not yielded to hygienic, medical and mechanical treatment, justify us in performing these operations, and to obtain the best results the cases must be selected, as was done by Dr. Johnson.

Dr. F. C. VALENTINE of New York.—I cannot agree with the author of the paper. In the largest service in Europe, castration has not been done for four years; this is true of Paris and Berlin. Vasectomy is also very rarely done, and then only when the patient demands operation. It has the appearance of being simply tentative. In the course of my studies in Paris and Berlin, it was a very easy matter to detect men who had been frequently catheterized, by an examination of the prostate, and I saw several in life who had regained as much use of the bladder as if they had been castrated. The results of castration have been discouraging to most men, and men who have had such invariably brilliant results have special skill, or are specially fortunately situated. I think it is time to be conservative, and in making up your mind to relieve a prostatic obstruction, do not always think it necessary to remove the testicles. Bearing in mind the unfavorable reports that we have of this operation, I would prefer to hesitate in performing it, and would certainly not do it until I had exhausted every other resource.

Dr. W. J. MAYO of Rochester, Minn.—I have had considerable experience with these cases in institutions with which I am connected, and it has been our rule to operate upon all patients that were otherwise well for the radical cure of hernia and in all of the cases in which there is prostatic hypertrophy we castrate at the same time. I have no doubt that many cases not operated upon die from strangulated hernia and obstruction. Our method relieves the hernia and the urinary difficulty at once. There is one variety that is somewhat difficult to handle and that is those cases complicated with unreducible hernia. Insane patients stand the operation well, except that the wound sites are very dirty and the skin in all of these patients is very oily. Before and after an operation for unreducible hernia, the patient should be kept in bed for some time on a modified diet.

Dr. JOHNSON in closing.—I am aware of the condition of the affairs in France and Berlin, and of the opinions of the leading men in this country and Europe. I have nothing further to say, except to refer to the conclusions in my paper.

SELECTIONS.

Treatment of Seasickness.—An experience of five years on a transatlantic steamship line ought to teach something about the therapeutics of this affection, and such an experience Dr. Hugh Taylor of Southampton, endeavors to convey to the *Lancet*. He says: The nausea and subsequent vomiting of the first few hours are to a passenger prone to this malady almost inevitable, but seldom require interference, though the retching may become distressingly violent and, if accompanied by streaks of hemorrhage, especially alarming to the patient. I have found that the best way of relieving this condition is to apply a mustard leaf to the epigastrium, to give a hypodermic injection of morphia, some crushed ice to suck, and to insist

on the recumbent position being maintained by the patient. A whiff of amyl nitrite or chloroform is often useful; alcohol is best avoided, though a little iced champagne may be sipped in very small quantities. The frequently present constipation must be relieved by an enema or suppository, as purgatives by the mouth will usually be quickly rejected. Too much must not, however, be expected of this or any other line of treatment, but the urgency of the symptoms usually abates in from twelve to forty-eight hours, the patient gradually acquiring that stability of the nervous system nautically termed "getting his sea legs." The cases of prolonged nausea and seasickness in which the patient refuses or rejects all food are very trying both to the invalid and to the surgeon. If the cabin is a fairly large one and is not crowded I think these cases do better in their berths than on deck, though meddlesome friends will urge them to go on deck, to "walk about," and to "fight against" the malady. This unequal combat generally ends in the victory of Father Neptune, and the vanquished one staggers or is carried below—sick, blue with cold, and generally wretched. Hot bottles, blankets, a little stimulant, hot beef-tea, will quickly make the patient more comfortable. For general fluid nourishment I use beef-juice, frequently retained, especially if the first two are mixed previously with a little powdered ice and administered in teaspoonful doses. If they are rejected they should be given again directly the fit of vomiting is over. As regards drugs I used with considerable success a prescription of chloroform, nux vomica, and compound tincture of lavender. An alkaline stomachic mixture with nux vomica is also useful after the acute symptoms have vanished; it assists a languid or capricious appetite. A dose of bromid of potassium and chloral or a hypodermic injection of morphia is beneficial at night, allaying restlessness and procuring sleep. In those cases which essay the ordinary saloon fare, anything in reason may be allowed them. One woman insisted that sauerkraut was the only thing which would relieve her, and it certainly on the trip in question seemed to stop the sickness, though it failed to do so on a subsequent one. Among adults there are some who, without any vomiting or nausea, suffer from persistent and severe headache and others who suffer from continuous intense giddiness; the former may derive benefit from phenacetin and caffeine, bromid and chloral, or from nitroglycerin. The discomfort of the latter is only alleviated by the maintenance of the horizontal position. Children rarely suffer from seasickness, they are sick for a few hours and then are soon running about. A gentle laxative to combat the costiveness usually induced in them by a sea voyage and a little bromid and chloral at night will soon put them right, as a rule. My voyages have never lasted longer than ten days, so that in the case of longer trips one's experience might probably be greatly modified. I have never seen the numerous "quack" remedies do the slightest good, nor have I ever seen the at one time much vaunted "chlorobrom" retained where bromide of potassium and chloral were rejected by the stomach. In conclusion, I would say that a farewell dinner or other jollification the day before commencing a sea voyage is to a person subject to seasickness the very worst possible preparation for it. A blue pill followed by a Seidlitz powder is far better, though certainly not so festive.

On "Seeing the Case a Little Sooner."—In the *Brooklyn Medical Journal*, July, Dr. W. L. Chapman reports a case of extensive necrosis of the bones of the hand following felon. The patient was a female, aged 30 years, and married. While dressing one of her children she pricked the end of her index-finger with a safety-pin. Severe pain set in within twenty-four hours, when she was awakened from sleep by a throbbing pain in the injured finger. Her family physician could not be found, so that a comparatively unknown physician of their neighborhood was called in. This physician properly diagnosed the case as a felon, made an incision of the last phalanx down to the periosteum and dressed the wound antiseptically. The dressings were repeated daily for three or four days, at the end of which time the entire hand was swollen and painful. The family discharged the first physician and sent for the writer of this paper, who found a general cellulitis of the hand. Incision of both palmar and dorsal aspects of the hand was performed and iodoform gauze inserted to secure drainage. The constitutional symptoms shortly abated, but

the wounds continued to discharge until three weeks later, when the middle phalanx fractured spontaneously. Two days later the physician amputated the finger, but finding the metacarpal bone involved, removed that also. The metacarpal bone was not largely affected, but the patient had become greatly debilitated and he was afraid to leave any affected bone behind. The family was very angry with the physician who first treated the case, and the later practitioners had some difficulty in dissuading them from bringing suit against him for damages. They were ignorant people, and attributed the loss of the finger to the unskillful treatment of the first physician. They could not have obtained any damages, as the physician had treated the case properly, but it might have put him in a most unpleasant predicament and done him unmerited injury. Dr. Chapman closes his report with the following observations as to the medico-ethic situation in this and similar cases: "There is no doubt that the family might readily have found a plenty of 'ambulance chasers,' or unscrupulous lawyers to take the case in the hope of scaring him into a settlement, and a careless remark from either of us would have caused them to undertake it. Many damage suits for malpractice are caused by the statements of the physician who saw the case at its termination. In order to relieve himself of any responsibility in the case, he throws the blame on the one who first attended the case. There is one statement occasionally made by physicians which is a disgrace to the medical profession, lowering to the one who makes it, and injurious to his colleagues; its use is altogether too common. It is, 'If I had only seen the case a little sooner.' The reason I speak of the medico-legal part of it is that there are two cases pending now for similar affections. One was lanced, but did not terminate so favorably; the patient died. The other one is just like it. I have not the privilege of mentioning these cases directly, as I heard of them through friends. The suits are about to be brought."

PRACTICAL NOTES.

The Value of Digitalis in Pneumonia.—Maragliano states that he has established beyond a doubt the specific action of digitalis on the pneumonia coccus. A very small amount will kill the cocci in a culture and also neutralize the toxicity of pneumonia toxin in injections. Owing to this effect of the digitalis in neutralizing both toxins, pneumonia patients are able to stand much larger doses of digitalis than healthy persons.—*Gaz. d. Osp. e d. Clin.*, No. 31.

The Choice of an Alkali in an Acid Dyspepsia is not an indifferent matter, as Dubard has established that the acidity and pyrosis connected with the presence of organic acids in the stomach are rendered more intense by sodium bicarbonate, while they are favorably affected by the magnesio calcareous powders. On the other hand, in true "hyperchlorhydria," especially when there is pylorism, the preparations of lime and magnesio aggravate these conditions, while sodium bicarbonate is beneficial.—*Semaine Méd.*, July 20.

Painful Dysphagia Evidence of Syphilis.—J. Garel calls attention to the fact that every person who complains that it has hurt him to swallow for the last few weeks, three at least, should be considered a syphilitic and treated accordingly. Syphilis can be diagnosed at once from this one symptom of persistent dysphagia at any stage. It is frequently the first or only symptom recognized by the patient. The pain vanishes with forty-eight hours' treatment with potassium iodid, unless it is due to that extremely rare cause, incipient cancer or tuberculosis of the throat, which can thus be differentiated.—*Semaine Méd.*, July 6.

Holocain.—Randolph (*Johns Hopkins Hospital Bulletin* for July) records fifty-four cases in the eye clinic with the use of holocain. He concludes that as an anesthetic it is sufficiently effective, and says: "In those cases where a test was made of the rapidity of its action, as for instance, in foreign bodies in the cornea, the quickness with which anesthesia was produced was striking. Whether the anesthesia produced after two minutes is sufficiently profound to guarantee a painless iridectomy or a satisfactory cataract extraction I did not determine, but in those cases where operations of this character were performed, and where the holocain was instilled just as we do cocaine, no difference was observed in the anesthesia from that produced by the latter."

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 27, 1898.

THE NATURE OF THE ANTAGONISM BETWEEN
TOXINS AND ANTITOXINS.

The antagonism of toxins and antitoxins is a subject in regard to which our actual knowledge has been limited thus far, and any contribution is therefore welcome. We know really very little about the true nature of these substances; our therapeutic acquaintance with their qualities has been gained by experiments suggested by empirical observation, not thought out and elaborated *a priori* from any actual knowledge of the true nature of the materials dealt with. The how and why there exists a therapeutic antagonism have been up to the present, mainly matters of conjecture, not of knowledge, and whether it is chemic or bio-chemic, or more strictly physiologic, has been disputed with more or less weight of argument on either side.

A late issue (August 4) of the English scientific publication "Nature" contains an abstract of a communication to the Royal Society, June 6, by Messrs. MARTIN and CHERRY that seems to add at least some facts on this matter of the antagonism of toxins and antitoxins. BEHRING, EHRLICH, KANTHACK and BRODIE had advocated the view that this antagonism was a chemic one, somewhat analogous to the neutralization of an alkali by an acid, while BUCHNER, CALMETTE, METCHNIKOFF and others have maintained that it is indirect, and operates through the cells of the organism. If, therefore, it can be proved that antitoxin neutralizes toxin outside of the body, *in vitro* and not necessarily *in corpore*, it would go far to establish the theory that the action was a chemic and not a physiologic one. CALMETTE had shown that in a mixture of cobra poison with a neutralizing

quantity of its antitoxin and heated to a temperature of 68 degrees C. for ten minutes, the toxin retained its powers, while the antitoxin was destroyed. The authors considered this experiment inconclusive, as not taking into account the element of time, which should be considered as well as that of temperature in estimating chemic action. They therefore made a series of experiments on guinea-pigs, with a mixture of one cubic centimeter of antitoxin to twice, three times, and four times the usual fatal dose of snake venom. In the control experiments with the venom only, all of the animals died within a few hours. The mixture was allowed to stand at the usual laboratory temperature of 20 degrees to 23 degrees C. for the period respectively of two, five, ten, fifteen and thirty minutes, then pipetted off and heated for ten minutes to a temperature of 68 degrees C. and then injected. The animals subjected to the mixture of the stronger doses of venom that had stood for ten minutes or less mostly died or were very seriously affected, all of those that received the fifteen-minute mixture survived, though two were sick, while the thirty-minute mixtures produced no symptoms whatever, as was also the case with a similar series of unheated mixtures in the same proportion that had been allowed to stand for eight minutes before injection. Similar results were obtained with diphtheria toxin and antitoxin.

These experiments seem to show as far as anything can that the neutralization of toxins may occur *in vitro* and that the vital processes in the organism or the body cells are not essential to the process, and unless we assume what appears hardly justifiable, considering the usual mode of its preparation, that the antitoxin itself possesses some vital properties that are active in it, it must be some sort of chemic reaction that takes place. MESSRS. MARTIN and CHERRY, however, have supplemented the above experiments with another that appears equally conclusive, but in a different way. The molecular sizes of diphtheria toxin and antitoxin appear to be quite different; the toxin passes freely through a film of gelatin in a Chamberland filter under pressure, while the antitoxin is retained. They took a solution of diphtheria toxin, equal to eight fatal doses per cubic centimeter, and mixed it with a sufficient amount of antitoxin to neutralize it, allowed the mixture to stand for two hours and then passed it through the gelatin filter. Varying quantities of this filtrate up to four cubic centimeters (= 32 fatal doses) were then injected into guinea pigs without bad results, not even a local edema was produced, and the animals thrived under the injections. The unavoidable conclusion from this experiment is that the toxin was neutralized before filtration, as, were it otherwise, there was nothing to prevent it passing through a filter, as it had been repeatedly observed to do in fresher mixtures.

While the investigations of MARTIN and CHERRY throw a very decided light on the nature of the

antagonism of toxins and antitoxins, and leave us to infer with almost a certainty that it is a chemic rather than a vital one, they still leave us almost as much as ever in the dark as regards the real character and nature of the two substances. This assumption that the toxin is an albumose is perhaps a reasonable one, more so, indeed, than the suggestion based only on the apparent size of its molecules, that antitoxin is a globulin. Whatever they may be, however, it is an important gain to know something more of the nature of their inter-reactions.

Although the reaction seems to be essentially a chemic one, it is also possible that it is especially favored by the vital processes within the body. When we consider the start that the toxins practically have in disease, it would appear probable that this must be the case to some extent, as otherwise the antitoxins could hardly be as effective as we find them to be, especially in diphtheria. In any case there is probably some natural resistance of the system to be accounted for in the practical problems of the action of these agents on the organism.

HAY FEVER.

Medical literature can give us no definite data as to when this peculiar affection was first regarded as a distinct and separate disease. Unmistakable cases were reported in the sixteenth century, and since that time the disease has been becoming steadily more and more prevalent. The fact that there is a hay fever association in this country, which has records of over two hundred thousand cases, will show how extremely common the affection is in the United States. Indeed, this country and England are its principal seats, the inhabitants of Germany, France and other countries of continental Europe affording comparatively few cases. It might be stated here as a rather curious fact that hay fever is but infrequently encountered among immigrant Germans (JACOBI) and French, even in the regions where native English and Americans are particularly prone to attacks.

Since its earliest discovery the cause or causes of hay fever have been enveloped in doubt. Every conceivable reason, from the blessed sunlight of heaven to peculiar odors of animals or flowers, has been eagerly accepted and as quickly rejected. It was only when the gloom of mysticism and empiricism began to give way to the light of earnest thought and scientific study that some order came out of chaos. It was early recognized that the disease occurred in several successive generations, so that heredity was looked upon as a factor of some importance. Its annual appearance in many sufferers not only on the same day, but at a certain fixed hour, has been noted by many observers; indeed, the victims themselves often predicted accurately the hour of their first sneeze. Cases are numerous of the influence of the smelling of a rose in the production of the disease,

and all are probably familiar with the case of MACKENZIE in which an attack was precipitated by his giving his patient an artificial rose to smell. Mere intelligent observation of a picture representing some farming scene has been a sufficient cause to bring on an attack. These and many other instances of a similar nature have proven beyond the question of a doubt the neurotic element of the disease. Among other predisposing causes might be mentioned the male sex and the white race, attacks being of exceeding rarity among negroes. Age does not exert much influence, all ages being susceptible; usually, however, the victim has been subject to several annual attacks before the middle period of life.

The symptoms on the part of the respiratory tract led to early explorations of the nasal cavity for possible cause. The observers were not disappointed; almost invariably the subjects of hay fever have had some pathologic condition existing in the nose; ulcer, polyp, hypertrophy or congestion of the turbinates, deviation of the septum, remains of adenoids in the nasopharynx, chronic nasopharyngitis, have all been noted by various writers. It might well be stated as an objection that the nose-and-throat man who can not find at least one of the above conditions in every case that presents itself should give up the specialty; so that possibly a pathologic nose does not play the important part it was formerly thought to.

Among other predisposing causes the one that has gained the most support of recent years was that advanced by BISHOP at the annual meeting of the AMERICAN MEDICAL ASSOCIATION in 1893. In his own words, "an excess of uric acid in the blood causes hay fever." He showed that many patients afflicted with hay fever have an excess of uric acid in the blood during the morning; further, that these were the ones that were attacked during the early morning hours. He thought the paroxysm of hay fever analogous to an attack of epilepsy superinduced by the irritation of some pathologic meningeal process, tumor, adhesion, or hypertrophied bone, and that an attack, itself caused by a setting free of uric acid, on account of the pathologic condition of the nose was determined to that area. BISHOP claims that his theory does not at all interfere with the neurotic theory, but on the other hand, seems to clear up some points previously obscure, as for instance the onset in the morning. He thought that with the correction of the possible pathologic nasal conditions present, the attacks were switched off, as it were, from involving the nose, but that the excess of uric acid in the blood would be certain to cause symptoms of uricacidemia elsewhere in the body. Naturally, then, he directed attention both to the cure of any nasal disease present and to the prevention of an abnormal quantity of uric acid in the system.

The exciting cause of the disease is undoubtedly the pollen of plants, as proved over thirty years by

the beautiful and laborious work of BLACKLEY. He demonstrated, to the satisfaction of the entire profession, the increase of pollen in the atmosphere at the time of the greatest prevalence of hay fever, and its gradual disappearance as the season verged toward fall.

TREATMENT OF ENTERIC FEVER BY SYSTEMATIC COLD BATHING.

Dr. WILSON of Philadelphia, who, as is well known, has, for a number of years, consistently practiced the treatment of typhoid fever by cold bathing in the German Hospital in Philadelphia, now reports¹ the statistics of 741 cases, of which 55 died, the mortality being 7.42 per cent. In these figures are included all the cases of typhoid fever which entered the hospital from Feb. 1, 1890, until Jan. 1, 1898, excepting one patient who entered one afternoon and died the following morning, the anatomic diagnosis being typhoid fever. This patient was not bathed.

An analysis of the cases of enteric fever for the years 1896 and 1897 is also presented. For the purpose of comparison there is appended the statistics of the three principal hospitals in Philadelphia for the year 1896. The average mortality of 403 cases in these hospitals was 9.92 per cent. In these institutions some cases are treated by systematic cold bathing according to BRAND's method, but this treatment is not general, and Dr. WILSON can not state what proportion of the cases are bathed and what treated upon other lines. During the same year 64 cases were treated in the German Hospital, with seven deaths, a mortality of 10.9 per cent. During 1896 2490 cases of typhoid fever were reported to the Board of Health at Philadelphia. The number of deaths was 402, mortality 15.14 per cent. In 1897 the mortality rate was 13.39 per cent.

In this article Dr. WILSON also describes certain modifications in the method as originally formulated by BRAND. These modifications have been gradually adopted as the result of experience.

1. At the beginning of the attack purgatives, especially calomel, sometimes in fractional doses, are given. Purgatives are not administered to those who enter after the tenth day of the disease.

2. Cold is applied to the abdomen in all cases of marked abdominal tenderness, pain and hemorrhage.

3. The treatment by systematic cold bathing is established as a routine method and is employed in all cases; the only contraindications are, speaking generally, the signs of peritonitis, hemorrhage, perforation. Appropriate medicines are administered in response to special indications. The proportion of cases requiring any medication whatever, has been found to be very small, not exceeding 10 per cent. As convalescence begins, dilute hydrochloric acid may be given for a short time, and later, if anemia is present, some form of iron.

4. The rule had been adopted, and is still in force, to repeat the bath whenever the axillary temperature reaches 101.4 degrees F. The baths are repeated whenever necessary at intervals of three hours. Formerly, however, baths were stopped as soon as the temperature ceased to go above this point. A very interesting observation led to a modification of this rule, viz.: quite frequently patients with a temperature lower than 101.4 degrees would ask for baths because of the greater comfort obtained. Hence there has been instituted the practice of giving one or two plunges a day during defervescence, and this has seemed to hasten convalescence.

5. The fever wards in the German Hospital are small, each containing six beds. The bath has been arranged at the end of the small ward; the graver cases are placed in the beds nearest the bath and carried by the attendants from the bed to the tub and back, while the milder cases and the improving patients walk to the bath with the assistance of the nurses. In all cases the improving and milder cases rise from their beds every three hours, are assisted to the tubs by the attendants and return the same way. In no instance has Dr. WILSON had any occasion to believe that this modification of BRAND's original formula, namely, that a movable bath tub be placed at the side of the bed, had any unfavorable effects. On the contrary, favorable influences upon the course of the disease have been noticed. In addition to these empiric reasons there are good theoretic reasons for certain changes in the traditional methods of treating cases of long acute febrile diseases. Among the complications of typhoid fever, bronchitis, bronchopneumonia and hypostatic congestion have always been prominent, no matter what the treatment. These phenomena are, to a certain extent at any rate, due to the progressive weakening of the heart and mechanical derangement of the circulation. Dr. WILSON also believes that the development of somnolence, intestinal paresis, etc., is favored by the log-like, passive recumbency of the typhoid patient. Muscular atrophy from disuse and deranged lymphatic circulation are also mentioned in this connection. The experience in the German Hospital seems to point to the fact that enforced continuous repose adds to the original disease secondary nutritional disturbances due to functional disuse.

6. The measure of success in the treatment by cold bathing is determined by the period in which it is begun. BRAND's claim that the mortality is practically nothing when the cases are treated by his method from the beginning can not be confirmed in ordinary hospitals, because cases do not come to the hospital in the beginning of the attack. Many observations, however, show that the earlier the treatment is begun the greater the reduction in the death-rate. Ordinarily the hospitals do not receive any cases of typhoid fever until toward the end of the first week, the great

¹ The Philadelphia Medical Journal, July 9, 1898.

majority later than this, and quite a number as late as the middle of the third week. At the same time there are many mild cases ("mild typhoid") admitted at any time during the progress of the disease, with so low temperature that but few baths are given. These cases would probably recover without any treatment at all.

Plainly, treatment by cold baths, begun late in the course of the disease, must largely fail as a general plan, and it is also plain that the bath treatment can not be claimed to shorten the course of mild cases of typhoid. Dr. WILSON believes, however, that these two groups of cases offset each other, and that the conclusions based upon statistics are justified.

VENEREAL DISEASE IN FICTION.

From SWIFT'S "Tale of a Tub" it is evident that it was in the early eighteenth century *en regle* for young men "seeing life," to contract gonorrhea as a necessary part of their sociologic experience. Dr. TOBIAS SMOLLETT, in the latter part of the same century, evidently also deemed it a necessary part of the social education of the young men. Roderick Random, while an apothecary's clerk, contracts gonorrhea as a necessary part of an amour. He cures himself and his female companion of this disease. She, a woman of good standing in society originally, has sunk into prostitution through seduction. According to her, in the eighteenth century, "The most fashionable woman of the town is as liable to contagion as one in a much humbler sphere. She infects her admirers; her situation is public; she is avoided, neglected, unable to support her usual appearance, which, however, she strives to maintain as long as possible; her credit fails; she is obliged to retrench and become a night-walker. Her malady gains ground; she tampers with her constitution and ruins it. She grows nauseous to everybody, finds herself reduced to a starving condition, is tempted to pick pockets, is detected, committed to Newgate, where she remains in a miserable condition till she is discharged because the plaintiff will not appear to prosecute her. Nobody will afford her lodging, the symptoms of her distemper have grown outrageous; she sues to be admitted into an hospital, where she is cured at the expense of her nose." Random's master, the apothecary, has a specific for venereal disease, which brought him in a great deal of money, that had no effect on tertiary accidents. This is not surprising, considering the proclivities of this apothecary for substitution. Venereal disease, impotence and seduction to sexual perversions are utilized by Dr. SMOLLETT, but only, however, as a realistic side issue in the retribution for sexual errors. This phase is only with SMOLLETT a part of the novel, for a purpose. In his day, Lock hospitals were frequently started by practitioners, ostensibly for charitable purposes, but really for the same object that dispensaries are started today. It is a singular fact,

however, that the prejudices in cities against these was in the eighteenth century, in England, much less than it is today.

In the late nineteenth century the employment of venereal disease to subserve the moral objects of a novel for a purpose has been revived by SARAH GRAND. Her first popular production, "The Heavenly Twins," dealt with the marital effects of syphilis acquired by the husband in youth. She assumes, however, that syphilis insontium is an impossibility and that the male is always to blame. The object of the introduction of the venereal element into "The Heavenly Twins," is to show that men of fast lives ran serious risks of infection with constitutional venereal disease. It further teaches the sound sociologic doctrine that girls should not allow themselves to be married to such men, even if they had reformed mentally, unless their physical cure was equally well established. A marriage occurs in "The Heavenly Twins," based on "love" between playmates. The child which results from this marriage is born "old," with a "cold in its head," and resembles "a speckled toad." An illegitimate child of the same father has identical characteristics. The wife becomes progressively pallid, weaker and irritable from the day of her marriage till after the birth of the child. Thereafter she becomes insane, with a psychosis of a type due to exhaustion, rapidly passing into dementia, and hence probably of luetic origin. Although the topic is dealt with by SARAH GRAND in a less revolting manner and with greater scientific probability than in CONAN DOYLE'S "Round the Red Lamp," where tertiary effects are carried in full luxuriance to the third generation, still the problem involved in marriages with victims of syphilis is stated with equal force in both. It is to be regretted, however, that neither of the two has the notion of introducing syphilis caught from the practice of kissing children, or from the employment of healthy women to wet-nurse a syphilitic child. It would appear more desirable, if venereal diseases must be utilized in fiction for sanitary and sociologic purposes, that the fiction should deal with those innocently acquired, since these are the most dangerous. Obstetric syphilis, contracted by the physician in the general practice of his profession, has often led to the moral downfalls of the onset of parietic dementia, and hence could not but furnish a valuable moral from a sanitary standpoint to the writers of the "novel with a purpose."

In her second volume, "The Beth Book," SARAH GRAND strikes at a revived prejudice against the adoption of the treatment of venereal disease as a specialty by physicians. As already stated, this prejudice was not strong in the English cities during the eighteenth century in proportion to its strength today. Just ere the outbreak of the fifteenth century epidemic of syphilis this prejudice was particularly rabid. On the modern principle of the effect of a new culture-medium on the microbe, the virulence of the epidemic

as contrasted with the centuries-old, practically edemic lues (BURET, "History of Syphilis") is readily explicable. This virulence, however, gave acute characters to the old disease. Society physicians, fearing ostracism, refused to treat a disease which they claimed was unknown to GALEN and abandoned the sufferer to the tender mercies of quacks and empirics. Among the ranks of the medical profession have always been heroes who refused to obey society's behest and neglect suffering even among the vicious and criminal. Prominent among these was that great reformer under the guise of satire, Dr. RABELAIS, whose generous disposition drew him toward this neglected class of patients. In 1538 he made great efforts to reform the abuse of mercury in the treatment of the syphilitic patients at Paris. RABELAIS says that he "has often seen syphilitics when greased with mercurial ointment, their faces on edge like a knife and their teeth clacking like the key-board of a broken-down organ." In the treatment of syphilis RABELAIS used mild mercurialization, guaiac and the hot air and other baths which had been previously recommended by TORELLA.

SARAH GRAND makes a plea similar to that of RABELAIS for the treatment of venereal diseases in special hospitals. The "Beth Book" deals with the social ostracism of a physician to a Lock Hospital because of the prejudice of the society people of the English countries against the practitioner of an admitted specialty of venereal diseases. Among the British squirearchy (as a rule the narrowest snobocrats of the English-speaking peoples) this prejudice flourishes in full luxuriance, stimulated by a Malthusian cant which the humane MALTHUS would have been the first to repudiate. It is to be especially regretted that the absence of special hospitals for venereal disease from most American cities, demonstrates that this prejudice exists to an enormous extent among the speculative commercial classes who practically rule the business end of public and private charity. The existence of innocently acquired venereal disease is a sufficiently potent argument against Malthusian cant of the type described. It is to be hoped that "The Beth Book" may accomplish some reform in the English-speaking countries in this particular, albeit the book, like "The Heavenly Twins," appeals in its style to the hysteric rather than to the well-balanced social reformer.

CHOLERA BELTS.

It is understood that the Army Medical Board consisting of Colonel DALLAS BACHE, Lieutenant-Colonel CHARLES SMART and Major WALTER REED, convened by the Secretary of War to consider the question as to whether or not the Government should issue the so-called "cholera bands" for the use of United States troops in the field, has made its report to the Surgeon-General of the Army. It appears that the board in-

vestigated the literature of the subject, including the latest and best works on military and general hygiene, and the writings of the authorities on tropical diseases to determine the precise grounds on which the popular impression of the value of the abdominal band was based, for the board recognized the existence of a general impression among the members of the medical profession as well as among the laity, that the protection afforded to the abdomen by the wearing of a flannel band of sufficient width is beneficial in warding off attacks of diarrhea and dysentery. It did not, however, find any conclusive evidence of the value of the band. The authorities on the diseases of tropical climates recommend its use as a sanitary precaution; but these authorities are almost without exception, English physicians, and their remarks have a special reference to the insufficient protection afforded by the regulation clothing of the British soldier. The highest English authority on both general and military hygiene says: "The soldier wears no drawers, but in reality it is just as important to cover the legs, thighs and hips with flannel as the upper part of the body. Drawers folding well over the abdomen form, with the long shirt, a double fold over that important part, and the necessity of the flannel belt is avoided." The English soldier, in temperate as well as tropical climates, is supplied with two abdominal flannel belts, for the reason that, during the night hours and while sleeping, the skirt of the shirt, not being held in place by the belt of the drawers, is liable to be drawn up, with a consequent risk of chill to the abdominal surface. The board invites attention to the fact that it has not been found necessary to issue abdominal bands to U. S. troops serving in Arizona and New Mexico, a climate in which there is marked variation between the diurnal and nocturnal temperature, and rapid evaporation from the surface of the body, owing to the extreme dryness of the atmosphere. The American soldier is provided with suitable woolen underclothing including shirt and drawers; the whole surface of his body is protected against sudden chilling, and the region of the abdomen guarded by two thicknesses of material. Under these conditions the board considers that there is no necessity for the issue of the so-called "cholera bands" for the use of the United States troops in the field.

CORRESPONDENCE.

The Medical Department of the Army.

FORT HAMILTON, N. Y., Aug. 15, 1898.

To the Editor:—After the published statements of General Sternberg, Lieut.-Col. Senn, Capt. Munson, U. S. A., and others, perhaps nothing further is needed to offset the prejudiced and sensational articles which have appeared in the daily press from correspondents and from certain hysteric members of the Red Cross, seeking to aggrandize their own services by belittling the work and results of the Medical Department of the Army. However, I will venture my mite. Sent to service

with troops in the field at the time war was declared, attached to regiments, and later a member of the staff of the Second Divisional Field Hospital, Fifth Army Corps, there has been abundant opportunity at Chickamauga Park, at Tampa, on the hospital ship *Olivette*, and in Cuba, from which I returned on July 19, to see the workings of the Department under many and varied exigencies incident to the adaptation of its organization from a peace to a war basis.

It is to be noted that until after the landing in Cuba there was a remarkable freedom from adverse criticism by the lay or medical press or individuals. On the contrary, remarks complimentary to a high degree were frequently heard from line officers, to the effect that if war had developed defects in other staff departments, it had shown the soundness and efficiency of this one. The medical officers of the regular army, who, under the scientific guidance of General Sternberg, had for years rigorously and at frequent intervals inspected the sanitary conditions of posts and camps, the food and clothing, analyzed the water-supply, and superintended the first-aid training of officers and enlisted men, continued their work at the Chickamauga and Tampa camps, and the records show how few men were left behind or accompanied the army of invasion with physical disabilities. While a great quantity of medical supplies were carried along on the *Olivette* and on the troop-ships, our ambulances and transport wagons, of which a sufficient number had been provided by Colonel Pope, U. S. A., the chief surgeon, were denied ship room.

During the long trip from Tampa to Baiquiri, the *Olivette*, commanded by Major A. H. Appel, with its eighty first cabin staterooms, accompanied the fleet, and whenever the sea permitted, received all sick from the crowded transports. Plenty of fresh air, ice, and suitable food brought about a speedy recovery in many men, who were consequently able to rejoin their companies on reaching land. At Baiquiri, as rapidly as men could be landed, they were pushed to the front with only travel rations, a change of underclothes and ammunition, leaving behind, in most cases, the medical stores of the regimental surgeons, either on the transports or along the shore where the small boats had dumped them. Dependent on other departments, its own means of transportation being perforce left far behind, the difficulties confronting the Medical Department of carrying tentage, cots and supplies along with the rapidly advancing army, and keeping everything in shape for the quick relief of the hundreds of wounded and sick men liable to be thrown on their hands at any hour, were truly immense, and reflection has not lessened my admiration for the executive work of men like Major Legard, Major Wood and Major Rafferty, who were burdened not only with their strictly professional duties, but with details of quartermaster and commissary work. However, a field hospital was on hand at the battle of Las Guasama, and the *Olivette*, steaming to Siboney, received on board the eighty wounded, of whom not one, to the best of my knowledge, has since died from his injury.

Personally present during part of the battle of San Juan, I was amazed and gratified not only at the intrepidity and dexterity of the regimental surgeons and their hospital corps men while under fire, in dressing the wounded, but in witnessing how quickly the wounds of hundreds who were placed hors de combat in a few hours were quickly protected by their comrades with sterilized first-aid dressings. The worst cases were treated at Major Wood's hospital, which was as near the front as the firing allowed. The others returned by ambulances or wagons to Siboney, where the second and third divisional field hospitals joined their forces. Here tentage for nearly a thousand patients had been erected. Of the necessary antiseptics, dressings and instruments there was a sufficient supply, though much still remained aboard several transports impossible of access, and the hospital ship *Relief*, under Major Torney,

U. S. A., arriving soon after the San Juan battle, brought a great quantity more. Only a few men in all reached the Siboney hospital without having previously received a first-aid dressing, and careful disinfection of wounds, dressings or operations were proceeded with as rapidly as was consistent with the patients' safety. I can speak with great pleasure of the uniform carefulness and attention to surgical cleanliness on the part of my colleagues, even when ready to drop from exhaustion incident to days and nights of almost continuous work. But one amputation from bullet wound and the very few cases of infected wounds speak volumes for their care and skill.

Upon the scene now appeared for the first time representatives of Clara Barton's Red Cross, who, with a doctor or two and several trained nurses, lent an assistance duly appreciated. It must not be for a moment forgotten, however, that what they did—and no one appreciates it more than those they directly aided—was but a drop in the bucket to what had been done and was being done by the Army organization. Suffering there was, of course. As Dr. Senn says, "war always has its hardships; it can not be prosecuted in parlor cars or club-houses;" and in spite of all defects and omissions incident to our first hurriedly prepared invasion of a foreign land, history, I think, will show that after no previous battle were the wounded tended so quickly, and with such good results and so little suffering.

Respectfully,
LOUIS P. SMITH,
First Lieutenant and Asst.-Surgeon U. S. A.

A Chair of Ethics in Medical Colleges.

TOLEDO, OHIO, Aug. 15, 1898.

To the Editor:—It goes with the saying that medical colleges are very largely responsible for conditions existing in the medical profession. Conditions, as used above, include many things, and the word "responsible," in this same sentence, points prideward as well as in the opposite direction. One condition, as the word is used, is the general intelligence of the medical profession; another, the standard of medical knowledge which maintains, while professional honor, honesty, morality, etc., are others.

Medical colleges are alike responsible for the highest grade in learning, uprightness and respectability, for example, as they are for the lowest grades in the same spheres. Naturally one looks for a college-bent principle to lean in the same direction throughout life, and the expectation is usually realized. There is among some members of the profession a positive antagonism to the "Code of Ethics." That antagonism had its origin some place, in some influence which was generated either by teaching or from observation, and medical colleges are in a great measure responsible for the existence of that unbelief. Like other evils, it would cost many times more to uproot it than it would have cost to have seen to the sowing of clean seed in the start.

Recently a physician said, during the session of a medical society, that he had been practicing medicine for thirty years, and that he had never so much as read the "Code of Ethics." There was an air of serenity about him which betokened a feeling of self-satisfaction within, and as he stood in contemplation of the example of a self-made ethical physician, which he presented to the society, the odds were, from his point of view so preponderantly against anything which the followers of the Code could adduce, that the expression of his face showed commiseration for that physician who had been under the dwarfing influences of the Code. Not much can be done with such a man. Probably the easiest way and best way is to leave him to the blissful enjoyment of his own company.

There are other kinds of anti-code men, and anti code men for other reasons. These men skirmish in their home societies during the year, and then have their annual round-up at the meetings of the A. M. A. There are all kinds of men at these

meetings, and one class get so tired of the yearly résumé of the various astigmatic visions which the Code reformers believe they have had during the year, that they say, "for the sake of harmony, for the sake of peace, for the sake of what we came here for, give them what they think they want." This class of men are loyal to the profession, to the Code, and to the A.M.A., but they are they who, because they have not much depth of earth (sand), when the heat comes, wither away, and the no-codists have the aid of their votes.

Another class, while not more loyal to the best interests of the profession, take life easier, that is to say, stand grief better, and upon the final vote, good-naturedly vote, "No," and then, as they should, dismiss the matter from their minds until some one of the reformers proceeds to remove the dressings from the imaginary sore, at the next session.

This class of physicians appreciate the fact that the no-codists are equally as scientific physicians as are those who uphold the Code. They know too, that they themselves have hobbies, and that if fifty or a hundred of them could but unite upon one particular hobby, they could make life as much of a burden for the members of the ASSOCIATION as the no-codists are doing; and so they charitably accept the situation as being one of the afflictions to which humanity is incident, giving thanks that their own erratic ideas are of such a nature as to make a combination with any other hobby impossible. There always have been no codists at the sessions of the A. M. A. and the no-codists emphatically assert that they are always going to be there, so it would seem that a meeting in which the Code question would have no place upon the program is past praying for; and really, to have the Code regularly scheduled as the subject for annual effervescence and defervescence is not the worst thing for the ASSOCIATION which can be thought of. Beside, it follows by no means, that if the Code question were strictly debarred from discussion there would be no time spent over ASSOCIATION rules and laws of government, because it is apparently the first thought of some men as soon as they become members of an organization, to look in the constitution and by-laws for something to amend or strike out, and it is better and safer for the ASSOCIATION, as now, to have a definite, well-understood subject the object of attack, than it would be to leave the undictated imagination to find a wrong whose victims would be crying to heaven for redress.

Some probably are kept away from the meetings by what they feel to be an unbrotherly contention, or a waste of valuable time, but quite as many others, if it were known that the code question would not come before the session in any form, would stay at home, so that the effect upon the number of members in attendance is a stand-off.

The object in having a Chair of Ethics established in medical colleges is not that such a chair would in any way seek to interfere with the no-codists' cherished right of the stated parade of their opinion, or in fact with anything else that they feel belongs to them, but the object is to inculcate the truths of the Code on the minds of students of medicine, precisely as the chair of anatomy builds up in the minds of students a knowledge of anatomy.

The anatomy of osteopaths, christian scientists, and what-nots, is a very different thing from anatomy as taught in medical colleges, and just so the no-codists exhibit their skeleton of the code, which everybody except themselves knows is not the frame-work of the Code of Medical Ethics at all. The chair of anatomy does not bother with osteopaths, etc., neither would the chair of ethics need to trouble itself with the no-codists. If a medical student were, once or twice a week, for four years, to listen to a lecture upon the Code, he would be at his graduation a better physician, a better citizen, a better man, than he would be without the lectures. There is abundant material about every medical college to illustrate

the teachings of the Code, and with a copy of the Code in the hand of each student, the professors would become exemplars of the Code, not that they are not such now, but, in a wider and deeper sense it would be more manifestly and specifically the appropriate thing that "the teachers of such things ought themselves so to walk."

For the demonstration of the operations of the Code, the clinic itself would furnish many object lessons. To most men the Code is a helpful looking glass. By it many removable defects are made visible, and these defects removed in student life would save much mortification that would otherwise be inevitable in later years. It costs something in temporary comfort, and in money also, to remove a blenish, but society as well as the afflicted one, in the end, is better off for the sacrifice.

The Code, like all other beneficent provisions, squarely antagonizes selfishness. There is a robustly modest denial of the existence of selfishness in any degree, in some sections of the East, but most men in their quiet moments can recall in some of their acts the workings of that subtle influence, and to such men the stimulation to greater carefulness, which the Code constantly begets, is an acknowledged help. Selfishness is in a way, cunning. Our own selfishness often deceives our very selves. More often it is, indeed, that it blinds and deceives us, than that others are fooled by it, hence it is that the easiest place to detect selfishness is in others. In a chair of ethics is a hitherto unused power which is potent for good to the medical profession.

What the condition of the profession would be to day, had such a chair always been in colleges, is a matter of guesswork; but because a chair of ethics never has existed is no reason why one should not be established.

The desirableness of a better knowledge of what the Code teaches, so that there may be a better measuring up to its standards, must be the excuse for having taken so much of your space in trying to outline the theme.

J. F. TRACY, M.D.

Congenital Absence of the Uterus and Anus, the Rectum Ending in the Vagina.

PAWNEE CITY, NEB., Aug. 10, 1898.

To the Editor:—After describing the more usual forms of malformations, Dr. C. A. Kelsey,¹ says: "In addition to these more common malformations there are various others. The anus may open by an abnormal anus at any point in the perineal or sacral regions, or it may end in the bladder, urethra or vagina." Bearing on this subject I wish to report the following interesting case which came under my observation:

Miss —, age 23 years, small of stature, of good family history, has one older sister who menstruated quite young; has never menstruated. About a year and a half ago she and her mother came to me with the following history: when she was born, it was discovered that there was no anal orifice and she was given up to die by the physicians, but after a few days straining the nurse noticed that a small amount of meconium was escaping from the vulvar orifice. This increased in quantity and she began to thrive, but had great trouble with her bowels until about ten years ago; had to use enemata or take salts to secure a passage. For the past few years she has not been troubled in this way, but when the bowels are loose can not control the movements well and in consequence sometimes soils her linen. When the bowels are not loose she has no trouble but must go on rather "short notice," sometimes. She further stated that for the past few months, she had at irregular intervals, experienced vague pains in her back and abdomen, which she thought were caused by the menstrual molimen, hence the consultation. On making a physical exam-

¹ Reference Hand Book, Vol. 1, page 287.

ination I noted the following: A well-formed girl, small of stature; weighing about one hundred pounds; mammae well-developed and perfectly formed; measurements with the pelometer showed the following dimensions: Across spines of the ilium, twenty-four centimeters; across from crest to crest, twenty-five centimeters; bis-trochanteric, thirty; conjugato (external), eighteen. The pudendum was covered with a normal growth of hair. The labia majora were hardly so full as the normal in one of her build. The nymphæ and clitoris were well-developed. On separating the nymphæ, a normal urethral meatus presented. The hymen was somewhat rudimentary but fairly well outlined and caruncular myrtiformes fairly well marked. The vestibule and fourchette were normal. In fact, the entire pudendum was normal.

Extending from the fourchette posteriorly for about two centimeters and about one centimeter in breadth, was a band of delicate skin, very closely allied to mucous membrane. From this back to the tip of the coccyx the appearance was that of a normal perineum, the skin containing the usual amount of pigment, but no signs of an effort at the formation of an anus. The ostium vaginae, in passing the finger, seemed quite normal, but after the examining finger had penetrated to the depth of two and a half or three centimeters, it came in contact with an annular constriction which was evidently the internal sphincter of the rectum. When told to contract the sphincter, its grasp was quite perceptible, but nothing like the force of the normal muscle. Just beyond this the finger came in contact with well-moulded feces and quite a roomy rectum. Bimanual palpation disclosed a narrow band running from one side of the pelvis to the other. On the left side, a quite movable body could be felt, which appeared about half the size of a normal ovary. This is undoubtedly a rudimentary ovary, as pressure on it causes that peculiar sensation complained of when the normal ovary is pressed. On the right side, occupying the same relative position, was a small, firm body about one centimeter in diameter. This was no doubt the rudimentary right ovary. There was no evidence of a uterus, except the narrow band which crosses the pelvis, corresponding to the upper border of the broad ligament. The bladder was normal in every respect, and a small speculum introduced showed the mucous membrane to resemble that of the rectum. From the explanation of the father, who had consulted me relative to the case before the patient presented herself, I had expected to find an *anus vestibularis*.

J. W. BULLARD, M.D.

A Leaf From an Old Book.

HUDSON CENTER, N. H., Aug. 15, 1898.

To the Editor:—There has recently come into my possession a book the title of which reads as follows: "Medicina Magica tamen Physica: Magical but Natural Physick, or a Methodical Tractate of Diastatical Physick. Containing the general Cures of all infirmities. With a Description of a most excellent Cordial out of Gold much to be estimated.

Published by Samuel Boulton, Salop, London. Printed by T. C. for N. Brook at the Angel in Cornhill, 1665."

The book is inscribed to the "Marquess of Dorchester," by Samuel Boulton, under date of 1646.

In these days of various "gold" treatments it may be of interest to become acquainted with methods employed 250 years ago. To quote our author: "Put foliated gold into a vessel well sealed with *Hermes* seal; put it into our fire till it be calcined to ashes; then sublime it into flores, having his *caput mortuum* or black *terra damnata* in the bottome; then let that which is sublimated be with the same degree of fire united to the same *caput mortuum* that it may be revived by it; so shall all may be reduced into an oyle which is called *Oleum Solis*; the dose hereof is 2 or 3 grains; And out of this *Mercury of Sol* thou maiest also by the spirit of wine extract

an high redness which will contain the cure of all diseases curable in nature, which is a true *aurum potabile*, and much to be estimated."

A most interesting feat of surgery is described as follows: "A certain man of *Bruxels* being at *Bologna* did in a fray lose his nose; and going to *Taylaicoza*, a Chyrurgeon living there, to consult how to have a new nose; and fearing the cutting a piece out of his own arm, he hired a porter for a good summe of money to have one cut out of his arm; which being done, and the cure performed, the man of *Bruxels* returned home."

This result appears to be eminently satisfactory and worthy of being ranked with the achievements of modern surgery, but note the after history of the case:

"About 13 months after, he felt his nose suddenly grow cold, and within a few days after it rotted and fell quite off; And he with many others, wondring at the strange chance, enquiring of the cause, it was found that just at the same instant that the nose grew cold, the Porter at *Bologna* died; the truth whereof, as *Helmont* writes, many at *Bruxels* will testify."

Our author shows true courage and approximates the modern standpoint in combating the then prevalent belief in the almost universal efficacy of blood-letting.

"Some say many have amended upon letting blood. I deny it not, but that was not the cause of the recovery, but natural heat, stirred up, set upon and conquered the disease, which heat might have been better stirred up, especially by Purgation at the beginning when there was strength; by which means also the cause of the disease being partly taken away, the part is much relieved. Thus you see the madness of them that are so forward upon every occasion, time, and age, to let blood; whereon, how many dangers follow, I appeal to Experience. And this is the true cause why Feavers are so seldom cured. I would physicians would follow nature, and leave off one to swear himself a slave to *Galen*, another to *Avicen*, a third to *Paracelsus*. These men were great, but when they strove to defend their owne Opinions, they often erred."

Let us allow our author to display his knowledge of physiology, by quoting his description of the urine: Urine is an Excrement of the second Concoction, done in the Liver, or rather in the Veines, from whence by the emulgent veins it is sent to the reins, yet mixt with blood, out of which by the Uriters it is as it were percolated and strained and so sent to the bladder, where also it abideth a while, and then is by its passage cast out; Hence it appears that the urine hath a great communion with most part of the body; for it hath great affinity with the Liver, Reins, and Bladder; for by these parts it passeth."

Perhaps the most interesting passage in the book is the description of the wonderful weapon salve compounded of brain tissue, Egyptain mummy, etc., mixed only when the auspices of the moon and planets are favorable, and applied daily, not to the wounded part but to the weapon with which the wound was inflicted.

HENRY O. SMITH, M.D.

Normal Salt Solution.

CHICAGO, Aug. 17, 1898.

To the Editor:—Have just been reading the really valuable article, "Saline Infusions" (*vide JOURNAL*, August 6, p. 306), and its suggestions will doubtless have great weight with many practitioners. In view of that fact, I thought it might be well to call attention to a typographic error in the fourth line from the top of page 307, where it directs a 6 per cent. salt solution when it should say .6 per cent. More especially did I think it necessary, since I saw no correction in last week's number. Life-saving measures ought to be well known, and this certainly is one.

Truly yours,

C. H. MILLER, M.D.

Of course our correspondent noticed what was so obvious

that the necessary punctuation mark in front of the figure six (.6) was omitted, and its absence escaped the attention of the proof-reader. But the formula was correctly stated in the preceding column of the same article, as a drachm to the pint. According to Foster ("Text-book of Physiol.") 0.6 per cent. is a normal solution. Howell ("Am. Text-book of Physiol.," p. 362) states 0.9 per cent. is the "physiologic salt solution." Foster's Dictionary states that a solution of $\frac{1}{2}$ to $\frac{3}{4}$ per cent. causes little or no change in animal tissues with which it comes in contact, and hence is called "indifferent" (or *normal* or *physiologic* salt solution), and is used in physiologic experiments and microscopy whenever it is desired to keep the tissues as nearly normal as possible (Wood, "Ref. Handbook"): Normal salt solution, gm. 15 to 2 liters.

Ethics as Practiced.

CONSHOHOCKEN, Pa., Aug. 15, 1898.

To the Editor:—It seems to me that this letter is a good text for an editorial on "Medical Ethics." Is this the ethics recognized by the New York profession and recommended by a teacher in a medical college, even though a subordinate?

Respectfully, GEO. M. STILES.

BROOKLYN, July 7, 1898.

To whom it may concern:—This is to certify that I am acquainted with the methods of the International Fidelity Rupture Cure Co., and am satisfied that it is a work which any doctor, whom this Co. may consider competent and reliable, can take up in connection with his regular practice, with great advantage to himself, and at the same time keep within the bounds of Professional Ethics. Yours respectfully,

HERBERT A. RUSSELL, M.D.,

Demonstrator of Anatomy at Long Island College Hospital.

P. S.—The above is a verbatim letter from Dr. Russell, who is using this treatment in connection with his practice.

NEW YORK, Aug. 13, 1898.

G. M. STILES, M.D., Conshohocken, Pa.

Dear Doctor:—We have a positive cure for all forms of hernia that can be retained with a support, and can demonstrate the truth of our assertions to your complete satisfaction. With the great number of people afflicted with hernia—at least one in every ten—here is a field that is practically unoccupied, and from which large fees are obtained. We receive from \$100 to \$500 for a guaranteed cure in adults. Children are cured for less.

You can use this treatment in connection with your practice and make from \$3000 to \$8000 per year; or, if you prefer to make a specialty of it, as many do, the income ranges from \$6000 to \$15,000 per year, and only a few hours each day are devoted to the work.

The pay is certain and prompt, and all the disagreeable features of a general practice are eliminated.

This treatment is strictly ethical, for there is nothing secret about it. To each physician engaging in the work, every part of it is explained explicitly.

If you are interested in this, and will write to us by return mail, we will give you all the information at our command, and will, if you desire, call upon you personally and explain to you our method of starting you in the business. Respectfully yours,

INTERNATIONAL FIDELITY RUPTURE CURE CO.,

Per B. H. TEMPLE.

Remarks of Dr. Egan at Detroit Conference.

SPRINGFIELD, ILL., Aug. 19, 1898.

To the Editor:—As my reply to the question asked at the recent Conference of States and Provincial Boards of Health at Detroit, relative to the principal line of work of the Illinois State Board of Health, is incorrectly reported in the JOURNAL of the 20th inst., I will ask you to kindly print my remarks in full, a copy of which accompanies this. Very truly yours,

J. A. EGAN, Sec. Ill. State Board of Health.

DR. J. A. EGAN I regret to state that the principal line of work of the Illinois State Board of Health is in connection with the enforcement of the Medical Practice Act, the duties pertaining to which have so increased during the past few years that the Board has really become one of registration and examination. It is earnestly hoped that before this Con-

ference again meets the law will be so changed that the Board will have an opportunity to perform its legitimate functions. Notwithstanding, that for years the Board has recommended the enactment of a law creating a State Board of Medical Examiners, to examine and license physicians and midwives, all efforts to obtain the desired legislation have been futile. There are, however, excellent reasons for believing that relief will be obtained during the coming year. As an illustration of the duties devolving on the Board incidental to the Act referred to, I will state that during the past year the Board has issued licenses to 875 physicians on presentation of diplomas and has examined 35 physicians whose diplomas are not accorded recognition. Fifty non-graduates in medicine and seventy-five midwives were also examined. During the same period the Secretary answered 11,473 communications, and the Board instituted prosecutions against 94 violators of the Medical Practice Act and took steps whereby 100 more were compelled to desist from practice. The above represents only a part of the duties occasioned by the Act. Aside from the maintenance of an efficient inspection and quarantine service at Cairo and other points in the southern portion of the State from September 7, the date on which yellow fever was announced as existing in New Orleans, to November 7, when the disease was entirely stamped out in Memphis, 100 miles south, very little outside of the ordinary routine work has been done by the Board in the line of sanitary investigation during the year. Whenever it has been found necessary or desirable, local boards of health have been assisted in the conduct of sanitary measures. All epidemic outbreaks throughout the State have been promptly investigated, and wherever no local boards of health existed efforts have been made to have such established. The sanitary condition of several of the State Institutions have been inspected, and in connection with the University of the State, analyses of the water supplies of the State have been made. Owing to a decision of the supreme court of the State adverse to the Board, no attempt has been made to enforce the school vaccination order, and on account of defects in the law creating the Board, it has been found impracticable to obtain any system of vital statistics. The existing conditions can be little bettered until legislation is obtained. The creation of a State Board of Medical Examiners is absolutely imperative, and sanitation would be much better promoted were laws also enacted establishing local boards of health, making the appointment mandatory, not optional as at present. There are several cities in the State, the populations of which run from 1000 to 10,000, which at present have no local boards of health.

PUBLIC HEALTH.

Bubonic Plague again Epidemic.—Press reports of August 17 quote official reports from Bombay, of the preceding week, as summing a total of 103 deaths (*vide* JOURNAL, Aug. 20, p. 429).

San Juan Board of Health.—General Miles has organized a board of health in San Juan: and when they are generally organized and are doing their good work all over Cuba, Porto Rico and the Philippines, the day of filth diseases and the deadly reign of General Bacillus will begin to be numbered.

A Coming Report on Typhoid Fever.—A Washington dispatch of August 17 states that Surgeon-General Sternberg has appointed a Commission to inquire into the cause and prevention of typhoid fever in camps. The commission will consist of Major Walter Reed, U. S. A.; Major Victor C. Vaughn, division surgeon of volunteers, of the University of Michigan, and Major Edward O. Shakespeare, brigade-surgeon, U. S. V. No more competent commission could have been selected.

New State Health Officer.—The Governor has named Walter Frazer Blunt, M.D., of Galveston, Texas, as State Health Officer to succeed the late Dr. Swearingen. In 1878 Dr. Blunt was appointed as State quarantine officer, and held the position for many years, first under State Health Officer Swearingen, then under Dr. Rutherford, and again under Dr. Swearingen. He resigned the position about eighteen months ago, being in ill health. During the quarantine troubles last fall he assisted Dr. Swearingen, and while Dr. Swearingen was so ill Dr. Blunt was called to Austin to take charge of the Health Department.

A New Focus of Endemic Bubonic Plague has been unearthed by R. Koch in the course of his travels in Africa. It is at Kiziba, on Lake Victoria Nyanza, and has hitherto been restricted to this locality, but there is danger of its spreading on the completion of the railroad now being built by the English to connect the lake with the Indian Ocean. The natives live almost exclusively on bananas, which they plant in groves so dense that no light nor air can penetrate, and these groves swarm with rats. Koch considers that effective measures will, in time, eradicate this disease, which is primarily a rat disease.

The Paris Sewage Park.—The luxuriance of the vegetation on these fields is remarkable; all kinds of vegetables, medicinal plants, etc., thrive to perfection, irrigated with water from the Paris sewers, which is so purified in its course that it emerges from the "park" limpid and pure, as visitors taste and exclaim. There is no perceptible odor except in the midst of a net-work of the irrigating canals, and a few steps beyond it is impossible to distinguish it. All fear of contaminating the atmosphere of the vicinity has proved groundless. The number of bacteria is reduced to approximate spring water, and the authorities claim that the infection of the Seine will diminish with increased areas appropriated for sewage parks, until it will cease altogether when all the sewer water from the city shall be spread out thus on the fields. The amount thus far utilized is 20,653 cubic meters to the hectare; there are 795 hectares devoted to the purpose.

Research Laboratories at London.—The new government laboratories in Clement's Inn are found to be a great convenience. No fewer than thirty-eight rooms, specially constructed and fitted with perfect appliances, are at the disposal of the staff. It appears that in 1867 the number of samples examined and reported upon was 9,055; in 1877, 14,024; in 1887, 39,244; and in the twelve months ended March of the present year, 64,664; of these, 28,875 were samples of beer and brewing material, 11,403 spirits, 14,872 snuff and tobacco, 41 coffee, 6,423 miscellaneous articles, and the standardization of excise instruments and 3,050 specimens of the contract supplies of government departments. The principal laboratory is specially adapted for the examination of beer and spirits. A set of rooms are used for the analysis of crown contract samples and of food and drugs as well as tobacco. The new building was constructed by the Board of Works at a cost of between £25,000 and £30,000.

Sanitary Workers Should be Divorced from Politics.—The Secretaro of the State Board of Health was re-elected for the fourteenth time, which is a highly appreciated compliment. He also, with the next issue of the *Bulletin*, will enter upon his twelfth consecutive year as editor thereof. This honor is not unusual, but is rather a practical exemplification of civil service principles. So far as we know, Dr. Pelletier, Province of Quebec; Dr. Bryce, Province of Ontario; Dr. Young of Maine; Dr. Watson of New Hampshire; Dr. Lindsley of Connecticut; Dr. Abbott of Massachusetts; Dr. Frazer of Delaware; Dr. Porter of Florida; Dr. McCormack of Kentucky; Dr. Laine of California; Dr. Jennings of Arkansas; Dr. Sewell of Colorado; Dr. Baker of Michigan; Dr. Johnson of Mississippi; Dr. Probst of Ohio; Dr. Swearingen of Texas and Dr. Lee of Pennsylvania have been the secretaries of their respective provinces and states since their State Boards of Health were organized. There were others, as Dr. Metcalf of Indiana, Dr. J. Berrien of Tennessee and Dr. Cochran of Alabama, who maintained like relations to their respective states until death terminated their services. The position is one that by common consent seems to be, and should be, awarded independent of politics, religion, or on purely personal grounds.—*Iowa Health Bulletin*.

Smallpox Prevalence in North Carolina.—The *Bulletin* of the State Board of Health of that State for July reports a material spread of variola, both as to increase of cases and of localities

infected. About the middle of July there was known to be four infected points in Iredell County; also at Asheville, 1 case, which is nearly well; Catawba, 6 cases in one family in the southeastern part of the county; Cleveland, in Rowan County, 7; Reidsville, 1; Durham, 1. When the superintendent of Rowan County was first notified of the existence of smallpox at Cleveland he found 20 cases, 13 of whom had recovered. They had been diagnosticated as chicken-pox, urticaria and pemphigus, and no precautions whatever were taken in consequence. The people, we are told, called it "elephant itch," not a bad name, as the eruption of smallpox is about the biggest thing of its class. A negro from Cleveland went to Reidsville and was there two days with an eruption of smallpox on him before he was discovered. During that time he went on an excursion and mingled promiscuously with his people. One of these who had been exposed went from Reidsville to Durham in the beginning of the eruption stage. Although sought for he was not found until next morning, after he had slept in the same room with several others. Reports from Asheville, Iredell County, generally, Cleveland and Durham, show everything in good shape except the reluctance in too many instances of the people to be vaccinated. The reports, however, from Catawba County and Reidsville are not at all satisfactory, and we fear a spread of the disease in these localities.

Relations and Conditions of the Soil to the Spread of Disease.—Dr. W. H. Welch has shown that the possibilities of infection from soil contaminated with disease germs are numerous, and often intricate. The list of diseases whose causation has been shown to stand under conditions in more or less direct relation to contamination of the ground with their specific germs is a long one. Among the more important may be mentioned malaria, typhoid fever, cholera, yellow fever, dysentery, tuberculosis and the summer diarrhea of infants. Experience teaches, unmistakably, that contamination of the soil with organic refuse favors the development and spread of such diseases as these, and that the drainage and purification of the soil by proper systems of sewerage are among the most effective measures for their prevention. No more instructive illustration of the value of modern methods of public sanitation can be found than the inability of Asiatic cholera to secure a foothold during the last two European epidemics in clean cities, with proper sewerage and water-supply, and its ravages in notoriously filthy or insanitary cities, such as Toulon, Marseilles, Naples, and formerly Hamburg. Authorities have differed as to the relative value of sewerage and of water-supply in influencing the prevalence of typhoid fever. We need not pause here to discuss the matter. Both factors are important; the drinking water usually the more important. But it is sufficient for our purpose to show that purification of the ground by proper disposal of sewage is not one of the factors in determining a reduction in the occurrence of typhoid fever and other diseases. It is by no means an easy matter in all cases to assign to each one of the various recognized elements which go to make up an entire system of satisfactory municipal sanitation its due share in the beneficial result, for it rarely happens that one is introduced by itself alone, and the harmonious working of the whole system is often necessary to secure the best results from the individual factors, such as pure water-supply, efficient sewerage, good drainage, cleanliness of streets, improvement or removal of insanitary quarters, thorough sanitary inspection of dairies and food stuffs, public disinfecting establishments, hospital for infectious diseases, municipal laboratories, etc. In some instances, however, the conditions have been such as to furnish conclusive demonstration of the separate influence of the introduction of effective sewerage upon the death-rate from typhoid fever.—*The Sanitary Record*.

SOCIETY NEWS.

American Microscopical Society.—The twenty-first annual meeting of this Society will be held in Syracuse, N. Y., Aug. 30, 31, and Sept. 1, 1898. Tuesday, August 30, 10 A.M., will occur the addresses of welcome, followed by the reading and discussion of papers. On the evening of Tuesday will occur the annual address by the acting president, Prof. V. A. Moore of Cornell University. Wednesday afternoon there will be given demonstrations of the projection microscope and of laboratory apparatus, and in the evening will occur the *soirée*. Thursday afternoon the Society will be shown much of interest in the New York State Institution for Feeble-Minded Children. The Vanderbilt Hotel will be headquarters, with a special rate of \$2 per day. A small dining-room, known as the "ordinary," will be reserved for the exclusive use of members. Owing to the State Fair, held in Syracuse from August 29 to September 3, a round-trip ticket from any station in New York State may be purchased for half the usual rate and 50 cents (which entitles the holder to one visit at the Fair). All interested persons are invited to be present, join the Society and read and discuss papers or demonstrate apparatus and methods. For particulars as to membership, etc., letters may be addressed to Prof. S. H. Gage, Ithaca, N. Y., or Dr. A. C. Mercer, Syracuse, N. Y.

The Fourth International Congress for the Study of Tuberculosis in Man and Animal, held in Paris, France, July 27 to August 2, concluded its sessions by adopting the following resolutions:

1. While awaiting the time when tuberculosis shall be included among the contagious diseases requiring official notification, all public places should be provided with hygienic cuspidors and placards warning against their disregard.
2. Public authorities everywhere are urged to set the example by installing hygienic cuspidors in all places under their jurisdiction, especially—and this is the most important feature of the reform in schools of all kinds.
3. Protesting against the admittance of tuberculous patients to institutions for convalescents open to patients with other diseases.
4. Urging the establishment of public free sanatoria and asylums for convalescent children.
5. Endorsing the founding of as large a number of small sanatoria as possible by private initiative on the part of physicians and also by the public.
6. Recommending periodic international reunions for the further study of tuberculosis and especially of its prophylaxis.
7. Endorsing the courses in hygiene recently inaugurated by the Antituberculosis League in Paris and urging their adoption elsewhere.
8. Requesting the authorities to investigate means to prevent the use of fraudulent tuberculin for the purpose of concealing the existence of tuberculosis in animals destined for export.

The Congress also proclaimed the urgent necessity of legislative measures requiring: 1. The separation of diseased from healthy animals. 2. The sale of diseased animals for any purpose except for slaughtering. 3. The constant surveillance of dairies and the immediate slaughter of every animal affected with tubercular mammitis. 4. The sterilization, or at least the pasteurization, of all milk used in the manufacture of butter or cheese on a large scale. 5. The universal adoption of a service of meat inspection on lines similar to those followed in Belgium the last few years. The Congress also passed a vote of thanks in recognition of the active support rendered the League in the prophylaxis of tuberculosis by the presidents of the French universities.

San Francisco County Medical Society.—The regular monthly meeting held August 2, was devoted to a discussion of "Cancer of the Stomach." Dr. Philip King Brown treated of the pathology, Dr. William Fitch Cheney the diagnosis and Dr. Emmet Rixford discussed the treatment, confining his remarks entirely to the surgical treatment, practically the only aspect of the subject. Dr. Brown said that while scirrhus was the most common form and adenocarcinoma the next most frequent variety

met with, but little attention had been given to the form of pigment-celled carcinoma which, though not at all common, still was met with occasionally and was deserving of more notice than generally given it by writers. He gave a careful résumé of the facts known as to the macro- and microscopic appearances of the various forms of cancer in this location. Dr. Cheney, in discussing the diagnosis, referred to the tabulated, though unpublished, results of an examination of 150 cases in which the disease was found 20 times to have appeared in a subject under 30 years (between 20 and 30), and 17 times between the ages of 30 and 40; these cases seem to somewhat controvert the accepted idea that the disease is very rare under the age of 30 years. Of these 150 cases, 11 gave a family history of cancer, showing that while the factor of heredity may be exaggerated in many instances, it is certainly an element to be considered. In no instance in this series of cases could it be ascertained that injury played any part as a causative factor. The symptom complained of as the most aggravating and prominent, in this same series of 150 cases, shows pain to take the first place, being noticed in 130; vomiting was complained of in 128; while a tumor had been noticed by the patient or was at once perceptible in 115 cases. Only 36 cases had vomited blood, indicating that this factor is not so common as generally supposed. Dyspepsia has been noticed and was aggravated in 38 cases. Pallor, loss of flesh and the cachexia should lead, if combined with any one of these symptoms, to a careful examination of the abdomen, the possibility of cancer being suspected. On examination, the abdomen should be carefully inspected, for it was found in 76 of the 150 cases that on careful examination, or rather on simple inspection, a tumor could be more or less well discerned; it may be that the tumor does not appear at first glance, but as the abdomen is longer inspected the shadowy outline will become evident. Simple inspection will very often reveal an abnormal pulsation of the abdominal aorta. The fact was accentuated that the tumor may be at the pylorus and yet be found in almost any part of the abdomen, for the reason that there is so often enlargement of the stomach, thus allowing the tumor to sag down or to assume a location quite other than would perhaps be expected; because the tumor is found at some point other than the true pyloric location, is not any evidence that it is not a tumor of the pylorus. The value of the abnormally increased peristaltic wave was pointed out, as showing the presence of an increased muscular action, or an unusual development of the muscular coats of the stomach contents through the lessened lumen of the pyloric orifice. This peristaltic wave may be stimulated by striking the abdomen with a wet towel, or by rather rough percussion. Inflation of the stomach, either by means of bicarbonate of soda and tartaric acid, or by gas direct, should always be resorted to; by this means we may clearly ascertain the presence of other tumors of metastatic origin. The proceeding of inflation is perfectly safe, in the doctor's opinion, and has nothing to discourage its use. On palpating the abdomen it may occur, and in fact does often occur, that the tumor will be outlined one day, and perhaps not the next; this should not be regarded as an unfavorable factor in the diagnosis, for many circumstances may prevent the discovery of a tumor on any particular occasion; if it be found once it will be found again if persistent effort is made. The chemic examination of the stomach contents and test meal, though it should always be undertaken, is not so fruitful of good results as could be desired. It should be accepted only as one link in the chain of evidence. Tissue fragments, too, do not always throw much light on the true condition, for the arrangement of the cells has a great deal to do with the diagnosis from this standpoint, and the cells derived from washings are almost always much broken up and disarranged. If a portion of cancerous growth can be obtained, of course the diagnosis presents no further difficulties. The matter of the differential diagnosis was brought out very forcibly and the many points to be considered were carefully outlined. Dr. Rixford, in dealing with the question of treatment had prepared a careful list of the various operations in chronologic order, that had been advanced and tried for relieving the condition of cancer of the stomach. In speaking of the difference in the percentage of mortality between the first operations and those of the present day in pylorotomy, the point was emphasized that early operation is of vital importance and has had as much as any one thing to do with the decreased mortality. It was very difficult to gain the consent of any patient at first for the operation. Dr. Rixford called attention to the reports at the late congress at Moscow, when the returns

from a large number of operators were given; pylorotomy resulted in a mortality of 37.0 per cent., while the palliative operation of gastro-enterostomy exhibited a mortality of but 25 per cent. Very few of the cases operated on have lived for more than two years; it is largely on this account that the majority of the English surgeons are not disposed to favor operative interference in cancer of the stomach. As for gastrectomy, the Doctor was of the opinion that the operation was too young to express any opinion as to its usefulness, but he was rather inclined to look upon it as an operation with a very limited field, and one that, after a while, would be seldom done. The subject was discussed at considerable length by Drs. J. Henry Barbat, F. B. Carpenter, Dudley Tait and others.

NECROLOGY.

FOSTER PRATT, M.D., of Kalamazoo, Mich., died August 12 of angina pectoris, while seated in his library at his home with the evening paper in his hand. He had a severe attack of a similar character on August 7, while visiting relatives in a neighboring city, from which he had not completely rallied, although he had been able to be out, and two days before his death was actively engaged in attending to his professional duties. Death came peacefully and without warning as he sat in the company of his wife. Dr. Pratt was born in Mt. Morris, N. Y., Jan. 9, 1823. He spent his boyhood days in New York, completing a course in the Franklin Academy and later became principal of the Angelica Academy, which position he held until compelled to give it up on account of sickness. In 1844 he went to West Virginia to take charge of a private school in Hampshire County. He there married Miss Mary L. Gamble, studied medicine with Dr. A. J. Sangster and later went to Philadelphia and was graduated from the University of Pennsylvania in 1849. He practiced in Virginia until 1856, when he came to Kalamazoo, where he has since continuously resided. He early established a large practice, but gave it up to accept a position as surgeon of the 13th Michigan Volunteer Regiment. His regiment participated in the battles of Pittsburg Landing in 1862, the engagements of Stone River, Chickamauga, Chattanooga, Lookout Mountain, Missionary Ridge and Sherman's march to the sea. In 1891 he was made president of the village of Kalamazoo and at numerous other times he has been placed in official capacities. To him the city is largely indebted for its present system of sewerage which was established while he was one of the Commissioners of Sewers. He also took a very important part and active interest in providing the city with its water-supply. He has been a member of the AMERICAN MEDICAL ASSOCIATION for twenty years and has been a member of its judicial council. He was an honorary member of the American Medico-Psychologic Association, was twice president of the local Medical Society, once vice-president and acting president of the State Medical Society and once its president by election. His contributions to literary papers and medical journals were highly valued. In 1882 he wrote a comprehensive review of that portion of the tenth census relating to criminals, paupers, insane, idiots, the blind, the deaf and dumb. He strongly advocated the idea of the restriction of indiscriminate immigration to the United States of objectionable persons or those having a tendency to produce criminals and dependents. He had decided literary tastes and was quite a politician. He was district delegate to the National Democratic Convention at New York in 1868, at Baltimore in 1872 and a delegate at large at Cincinnati in 1880. In his early days he was a political speaker and a fine orator. He was prominent in Masonry, and while secretary of the Grand Lodge, he wrote the present code of Masonic Laws for the Michigan Jurisdiction. In 1858 Dr. Pratt was elected to the Legislature, and at the session of 1859 secured by zealous and hard work the first appropriation of any magnitude for the Michigan Asylum for the Insane at Kalamazoo. From that time on he was a staunch and steadfast friend and worker for the asylum.

When Dr. E. H. VanDeusen, its former superintendent, was sued for false imprisonment for detaining a patient in whose commitment papers there was some slight irregularity, Dr. Pratt was the earnest and helpful adviser of the asylum and, largely by reason of his suggestions and directions, the asylum was victorious in a very tedious lawsuit. In 1882 Dr. Pratt became a member of the Board of Trustees of the asylum, which position he occupied for twelve years, being president of the Board for four years. Since 1887 he has been a member of the local Pension Examining Board. Dr. Pratt was a man respected by all who knew him, a man of high and honorable aims and virtues, one whose faults were few and small. As a citizen and a friend he is held in tender remembrance by all who knew him.

WILLIAM CARTER OTTERSON, M.D., College of Physicians and Surgeons, N. Y., 1853, died at his summer home in Long Branch, N. J., August 17. He was a son of Rev. James Otterson and was born in Roslyn, Long Island, Sept. 17, 1828. During the Civil War he served as surgeon U. S. V. from Dec. 24, 1861, to May 25, 1864. Five years ago he gave up the duties of his profession in consequence of paralysis of the right side, after having practiced twenty-five years in Brooklyn, N. Y., at one address. Two sons and a daughter are his survivors.

OWEN J. WARD, M.D., N. Y. University Medical College, 1865, died at his home in New York city August 17, aged 58 years. He served on the visiting staff of the Gouverneur St. Hospital from the date of its establishment until his death.

W. J. CANNON, M.D., Lambert, Tenn., August 14.—George E. Catlin, M.D., Lake Geneva, Wis., aged 58 years.—Harlow P. Gamwell, M.D., Westfield, Mass., August 12, aged 74 years.—Edwin Gibbs, M.D., Washington, D. C., August 15, at Lynwood, Va.—Benjamin F. Wright, M.D., Youngs, Ga., August 10.

MISCELLANY.

An Advance in Therapeutics.—A New York physician, of course in an absent-minded way, prescribed protocol, grs. x, as the latest anodyne. He had been reading the war news.

A Prohibitive Tax.—Prof. Enrico Bottini, an Italian surgeon, announces in a public card his retirement from practice because "he was oppressed by the weight of the income tax imposed and was no longer able to meet it."

Antistreptococcus.—Marmorek's new antitoxin for the streptococcus pyogenes is proving successful in the tests at the Paris hospitals in septic wound and puerperal fevers, blood poisoning and other diseases caused by this streptococcus, and also in the complications of diphtheria, against which the Behring antitoxin is powerless.—*St. Petersb. Med. Woch.*, July 11.

Patent on Antitoxin.—Concerning the recent patent granted Prof. Behring, on antitoxin, Messrs. Parke, Davis & Co. of Detroit announce that they will protect and defend purchasers from any legal proceedings brought as a result of their purchase, sale, and use of their serum, having retained the services of Messrs. Betts, Betts, Sheffield & Betts, of New York City, patent lawyers, to fight the monopoly on antitoxin.

Ohio Medical College.—The *Times-Star*, Cincinnati, August 15, says: "They apologize—The AMERICAN MEDICAL ASSOCIATION has apologized to the Ohio Medical College for ousting them from the ASSOCIATION a year ago." This item only shows the ignorance of the *Star* in confounding the AMERICAN MEDICAL ASSOCIATION with the Association of American Medical Colleges, an entirely separate body.

The St. Louis Eye, Ear, Nose and Throat Hospital.—This hospital, located at 500 N. Jefferson Avenue, was opened to the public, April 1, 1898. The Eye Department is in charge of Dr. J. Ellis Jennings, and the Ear, Nose and Throat Department in charge of Dr. Leo Caplan. The ground floor is en-

tirely devoted to the out-door department, and is open to the poor from 2 to 4 P.M. daily, except Sunday. Care is taken to exclude from free treatment persons able to pay for professional services. The institution will be incorporated and have the privilege of giving post-graduate courses in diseases of the eye, ear, nose and throat, and of issuing certificates or diplomas to those who have taken the courses.

Nervous Phenomena in Children.—Willits (*Phil. Med. Jour.*, for August 6) says that a perfectly healthy infant should sleep twenty of the twenty-four hours. He condemns the practice of suddenly waking a babe from a sound sleep, so often done for visitors to talk and play with it, as this excitation falls directly on the nervous system and is an important factor in producing nervousness. Startling noises of any sort, as street noises, loud-striking clocks, bells, etc., are to be avoided.

Subclavian Aneurysm.—Moynihan (*Annals of Surgery* for July) discusses the treatment by both excision of the sac and the use of the distal ligature. He advocates the former method and claims for it a far greater chance of recovery, no risk of recurrence, less risk of gangrene, and a probable complete recovery from any affections due to nerve interference. He gives statistics concerning the mortality, gangrene and recurrence after operation in both of these methods, recurrence after operation being noted in 5 per cent. of the cases after ligature.

Medico-Legal Surgery.—The September number of the *Medico-Legal Journal* will contain an article on "The Progress of Medico-Legal Surgery," by the editor, Clark Bell, advance sheets of which have been sent to the *JOURNAL*. It gives a sketch of the organization of the Army and Navy Medical Corps and a full account of railway surgery in the United States and of its societies and associations, including the Section of Medico-Legal Surgery of the Medico-Legal Society, which is largely a body of railway surgeons. The article gives, briefly, a statement of the advances in surgery since the Civil War, and a series of letters from eminent surgeons with their opinions in regard to this subject, and would be a useful one for reference as to questions of military, navy and especially railway medical organizations in this country.

Thyroid Medication is generally considered injurious in exophthalmic goiter, but O. Martin urges all to cautiously try it in this disease before resorting to severer measures, as he has witnessed a number of severe typical cases permanently cured with this alone. He describes one of them in the *Presse Méd.* of July 13, nothing left but a slight tremor after four months of 40 to 20 centigrams a day of the dessicated thyroid extract. It has also proved effective in chlorosis. Capitan relates a number of cases which had resisted iron and tonics, but yielded at last to thyroid medication, indicating a thyroid origin for certain forms of this disease.

Township Trustee can not Bind County to Pay.—Section 6718 of Burns' Revised Statutes of Indiana of 1894, provides that the board of commissioners of each county shall constitute a board of health ex-officio for the county, whose duty it shall be to protect the public health, by removal of all causes of diseases when known, and in all cases to take prompt action to arrest the spread of contagious diseases, etc. But the appellate court of Indiana holds, in the case of Board of Commissioners of Perry County vs. Bader, June, 1898, that a claim for services as watchman during time of quarantine against smallpox, rendered by order of the township trustee, can not be collected from the county, through the board of commissioners, it showing no liability upon the part of the county.

An Ancient Hospital.—At Baden, near Zurich, Switzerland, in connection with recent excavations at Windisch, the Roman Vindonissa, an ancient military hospital has been discovered. It has fourteen rooms, which appear to have been well supplied

with medical, surgical and pharmaceutic apparatus, including probes, tubes, forceps, cauterizing implements, and even safety-pins; medicine spoons of bone, silver measuring vessels, jars and pots for ointments, etc. Some coins were also found, those of silver being of the reign of Vespasian and Hadrian, those of copper bearing the effigy of Cladius, Nero and Domitian. At Vindonissa, two great Roman military roads meet, one leading from the great St. Bernard along Lake Leman and then by Aventicum and Vindonissa to the Roman stations on the Rhine; the other from Italy to Lake Constance by the Rhaetian Alps, the present canton of Winterthur, Baden and Windisch. This last point was the station of the seventh and eighth legions.—*Scientific American*, Aug. 13.

A Skeptic in Georgia.—We once heard a very eminent and scholarly Bishop say that, in his experience, some learned men were the greatest fools. We do not care to apply this harshly to Prof. Koch, but will mildly suggest that he is out of his reckoning. Prof. Koch of antituberculosis fame has made a new discovery. He has come forward with the startling announcement that he knows what causes malaria. It's mosquitoes. He might just as well have included sandflies, gnats, and bedbugs. The *New York Times* cleverly turns the tables upon the professor. It says: "Now, Prof. Koch may be a very great man, but he has simply begged the question. If mosquitoes cause malaria, what causes mosquitoes? That's what this patient world wishes to know. Tell us how to get rid of the mosquitoes, and we shall not worry about the malaria." The presumed origin of the mosquitoes is water, yet Dr. Koch insists that malaria is not water-borne. The facts are against him, but just now he has his mosquito theory in full blast.—*Augusta Chronicle*.

Gynecologic Surgery of the Insane.—Hobbs (*Am. Jour. of Obstet.* for August), in a paper on "Surgical Treatment of Patients at the Asylum for Insane," London, Ont., says that "the work in gynecologic lines shows that perhaps one-sixth, if not one-fourth, of all the women in asylums for the insane are there because of the special infirmities of their sex." Of 136 women, 126—17 per cent. of the female inmates—had organic lesions or malformations incompatible with normal genitalia. Of the 126, the condition of 121 necessitated operative measures for the amelioration of physical disorders which either caused or complicated disturbance of the nerve centers. The impossibility of obtaining reliable data from the insane as to the origin of the ill-health made actual examination necessary, and always under anesthesia, ether being used, and, in these patients, being rapidly recovered from and rarely causing nausea or vomiting.

Speech Defects.—Scheppegrell (*New Orleans Med. and Surg. Jour.* for August) writes on the etiology and treatment of stuttering, stammering, etc., and groups the forms of speech defects in two classes: paralalia and dyslalia, the former referring to defective speech, lisping, etc., and the latter to difficult or spasmodic speech, as stammering and stuttering. He considers prophylaxis of the utmost importance, and believes the inclination of mothers to teach their children "baby talk" can not be too severely condemned, as they become so accustomed to this method of speech as to make it difficult to change it. He points out that girls suffer less from the more severe forms of speech defects than boys, and some authors have even doubted the existence of female stutterers, while Cöen of Vienna, places the number at only 1.5 per cent. of the whole number affected. He says that children should not be allowed to associate with stammerers, as the children may not only be influenced but there is also a tendency to aggravate the defect in the case of the stammerer.

Exhibition of Rupture to Jury.—In the personal injury case of what is now styled the Chicago & Alton Railroad Company vs. Clausen, in which the supreme court of Illinois affirmed a judg-

ment against the railroad company, and denied a rehearing, June 10, 1898, it was complained that the trial court had improperly permitted the plaintiff below to exhibit to the jury a rupture alleged to have been caused by the accident set forth in the case. This leads the supreme court to say that it is primarily within the discretion of the trial court to permit an injury to be shown to the jury for any legitimate and proper purpose that will aid in the determination of the issue: and that, while it is questionable whether the exhibition referred to was proper, inasmuch as the existence of the rupture, and the nature and extent of it, were not controverted by the defendant, and it is questionable whether its only effect would not be to excite feeling, rather than to aid in settling any disputed question, the court does not feel prepared to say that such was the case, or that there was a clear abuse of the discretion confided to the trial court.

A Medical Relief Yacht.—Mr. Alexander Van Rensselaer's yacht *May*, the services of which were tendered the United States Government by the owner, sailed August 5, for Porto Rico. It has aboard the four special commissioners appointed by the National Relief Association: Hon. William Potter, ex-Minister to Italy, chairman; Mr. Alexander Van Rensselaer, Mr. Louis C. Vanuxem and Dr. G. G. Groff. The yacht will carry supplies for the soldiers, which, by order of Surgeon-General Sternberg, will be placed at the disposal of Colonel Greenleaf, Chief Surgeon of the troops under General Miles' command. Having discharged the supplies, the yacht will carry to the United States any sick or wounded soldiers or sailors that may be awaiting transportation.—(*Phila. Med. Journal*, August 6.) [The press dispatches of August 20 noted the arrival of the vessel at Ponce. Mrs. Van Rensselaer was slightly injured by a stumbling horse while riding from Ponce to the military camp.]

New Medical Faculty.—The faculty of the Baltimore Medical University, which had been depleted by the resignation of a number of its members, has been reorganized with the following roster: Jas. G. Linthicum, emeritus professor of principles and practice of medicine. Hampson H. Biedler, principles and practice of surgery and clinical surgery. Wm. A. B. Sellman, diseases of women and children. J. W. C. Cuddy, theory and practice of medicine and clinical medicine. E. Reid, diseases of the nervous system and diseases of the throat and chest. Frederick C. Jewett, physiology and hygiene. Theodore Cook, Jr., diseases of the eye and ear. A. G. Barret, toxicology and chemistry. Z. K. Wiley, anatomy and pathology. C. Urban Smith, materia medica and therapeutics and clinical professor of diseases of the stomach. The adjunct faculty is: H. J. Hankel, demonstrator of anatomy. Howard Bryant, lecturer on medical jurisprudence. Shelton Law, lecturer on minor surgery and bandaging. S. Leroy Robinson, lecturer on practical pharmacy. H. A. Huland, assistant demonstrator of anatomy. J. T. McCarthy, lecturer on diseases of the skin. N. J. Kaeten, lecturer on histology and bacteriology. M. J. Kelley, demonstrator of pathology. Edward C. Moriarity, assistant demonstrator of pathology. J. J. Valentini, lecturer on diseases of nose, throat and chest. Geo. W. Lautenbach, assistant to the chair of nose, throat and chest. W. J. Chappell, lecturer on diseases of nervous system. George A. Strause, lecturer on applied therapeutics. Thos. A. Poole, assistant to chair of eye and nose.—*Baltimore News*.

Presumption as to Qualification of Physician.—The rule seems to be that, when the question of license arises collaterally in a civil action between the physician and one who employs him, due qualification under the statute will be presumed, and the burden of proof is upon him who denies such license. So says the supreme court of Iowa, in the late case of Kossuth County. But when it comes to proving the incompetency of a physician, as of one employed by the board of supervisors to furnish poor

persons in the county with medicine and medical aid, so that another physician employed by the township trustees to attend a pauper may recover of the county therefor, the court holds that the same rule applies as where the character of a person is directly in issue, and that the evidence must be confined to general reputation, and particular acts or specific facts are not admissible. And under this rule, the mere individual opinion of the witness is not admissible, and no one will be permitted to speak affirmatively to the character or competency of another, as distinguished from general reputation, solely from rumors or reports. The court can not try collaterally each and every case tending to show the ability or competency of the person whose skill is the subject of inquiry, and, before one is permitted to speak of the character or competency of another, knowledge must appear.

The National Relief Committee on Pure Water for Troops.—The National Relief Committee, through Dr. E. O. Shakespeare, the chairman of its committee on sanitation, has issued a pamphlet address under the title of "Pure, Wholesome Water for all Troops" in which, after showing what has been done by the Surgeon General and the Quartermaster-General of the Army to provide germ-free filtered water for a certain portion of the army, it urges the necessity for boiling all water not thus filtered. It then discusses the necessity for aerating the boiled water to render it palatable and makes various suggestions for accomplishing this. The Committee has adopted the following resolutions:

WHEREAS, in the opinion of the Executive Committee of the National Relief Commission, the supply of the American Armies with germ-free and palatable drinking water is so essential to the maintenance of the health and strength of the men,

Resolved, That the action of the Government in providing the means of furnishing 50,000 of our troops with germ-free drinking water should be most heartily commended; but we would at the same time most earnestly urge upon the responsible authorities at Washington, the necessity of providing, at the earliest possible moment, the means of furnishing the remainder of our armies, namely the other 200,000 men, with equally wholesome quality.

Resolved, That this body hereby expresses its willingness and desire to co-operate in such an effort to the extent of its ability and in any manner possible.

In carrying the last resolution into practical effect the committee on sanitation has communicated with commanding and sanitary officers of armies in the field, inviting attention to the necessity of boiling and aerating the water-supplies of camps, and requesting their views as to the best methods of effecting the purification of natural waters. Meanwhile, it has sent a special commissioner, Mr. Louis C. Vanuxem, to Porto Rico with supplies for the benefit of the hospitals there; and in view of the probable need for apparatus for purifying the drinking water, it proposes sending facilities for furnishing 5000 men with wholesome and palatable water, irrespective of the original quality of the natural supply. The apparatus comprises fifty water boilers, each encased in a removable wooden box for safe transport. Each boiler is about 20 by 11 by 13½ inches, fitted with hinged handles for convenience of transportation and with a rose sprinkling attachment, by passing through which the boiled water, when cooled, may be aerated to ensure palatability. A suggestion is made that this aeration may be effected by pumping air through a rose nozzle from such a pump as is used to inflate bicycle tires.

Standard Medical Works as Evidence.—The theory of the plaintiff in the recent personal injury case of Bixby vs. the Omaha and Council Bluffs Railway and Bridge Company, was that he had received a serious shock to his nervous system in a collision of street-car and railway train, and had symptoms indicating locomotor ataxia or some neurotic trouble, although at the time of the trial there was no objective or external evidence of any injury. One physician testified to such symptoms, while three

others insisted that there existed no signs of any disease. Then the plaintiff was permitted, over the objection of the defendant, to read in evidence extracts from a number of admittedly standard medical works, the portions read to the jury treating of the symptoms, and not the cure, of diseases. But the supreme court of Iowa holds that this was reversible error. It says that the question is not whether the courts will use the helps of science in the investigation of truth. There is no controversy on that score. The authorities are agreed that the truths of the exact sciences, the established facts of history, and computations from fixed data may be proven by the works of reputable authorities. This is on the ground that all men assent to their correctness. But it points out that medicine belongs to the class known as inductive sciences. The data are constantly shifting with new discoveries, and the conclusion which may be considered sound today is repudiated tomorrow. A medical work may be standard this year, and obsolete next. And even the opinion of the same author changes in the different editions, owing to new discoveries and a better understanding of symptoms. These facts, with the added one of difficulty often experienced by those learned in medicine to determine from the books the nature and extent of injuries and diseases, the court insists, emphasize the necessity of cross-examination and the use of an oath, not only that the theory contained in the books may be known and understood, but that practical skill may apply the science of medicine in each case. Nor does it consider that the admission of medical treatises is authorized by section 4518 of the Iowa code, which says: "Historical works, books of science and art, and published maps or charts, when made by persons indifferent between the parties, are presumptive evidence of facts of general notoriety of interest therein stated." But the court suggests that the same reasoning does not apply to a case where a physician is employed to treat a patient according to a certain system, so that, in determining whether he has in fact followed that system, the books from which physicians of that school are shown to have derived their knowledge may be admissible, for these expound the very principles which he is alleged to have violated; and, under the circumstances, the books themselves would be better evidence than quotations from them. But in Alabama alone, it is said, are medical works received in evidence for general purposes.

Hospitals.

THE new Sternberg hospital only a short distance from Lytle, Ga., was thrown open for the reception of the sick at Camp Thomas, August 16. The hospital has accommodations for 1200, and a corps of Red Cross nurses is in attendance.

OTTO YOUNG has donated a \$50,000 building, fully equipped, to the Chicago Home for Incurables as a consumptive ward.

Societies.

The following recent meetings are noted:

Indiana.—Southern Indiana Medical Society, Indiana Springs, August 12.

Iowa.—Southwestern Iowa Medical Association, Council Bluffs, August 18.

Michigan.—Grand River Valley Medical Society, Holland, August 9.

Ohio.—Muskingum County Medical Society, Signal, August 11.

Pennsylvania.—Cecil County Medical Society, Perryville, August 12; Lycoming County Medical Society, Williamsport, August 12.

Virginia.—Richmond Academy of Medicine and Surgery, August 9.

Louisville.

RODMAN.—Dr. Wm. L. Rodman, former Professor of Surgery in the Kentucky School of Medicine, will remove September 1 to Philadelphia, where he goes to accept the chair of Surgery in the Medico-Chirurgical College. Dr. Rodman filled the

chair during the last college term, but returned to Louisville at the conclusion of it; he now goes permanently.

NOVEL EXPERIENCE.—Dr. S. J. Meyers, at home on sick-leave from his post at Camp Thomas Division Hospital, relates the following experience, which is decidedly original and uncommon in army hospitals: He had hardly been in the camp two hours when he had delivered a woman of a premature fetus. Standing at headquarters a soldier rode up in great haste stating that a woman was dying in another part of the camp, and soliciting medical aid. The Major commanding the hospital sent Dr. Myers with instructions to do all he could for the patient without assuming any responsibility. The Doctor found one of the actresses at the camp theater in labor, and delivered her in a few moments of an eight months' fetus which was dead. The mother stated she did not know she was pregnant and had not lost a moment's time from her work to the time of her delivery. A labor case in an army camp of 45,000 men is something of a novelty.

Washington.

HEALTH OF THE DISTRICT.—The report of the health officer for the week ended August 13 shows the total number of deaths to have been 96, of which number 51 were white and 45 colored. The principal causes of death were: Nervous diseases, 13; heart diseases, 7; intestinal, 4; respiratory, 17. There were 2 deaths from diphtheria and 1 each from measles and typhoid fever. At the close of the week there were 28 cases each of scarlet fever and diphtheria under treatment.

PHYSICIANS TO THE POOR.—Drs. H. T. Harding and P. C. Hunt have been appointed physicians to the poor, at a salary of \$30 per month. Dr. E. A. Gorman has been appointed resident physician of the Washington Asylum, vice S. C. Johnson resigned. Dr. J. Spence Hough of the health office, who was appointed a surgeon in the navy for duty on the steamer *Morrill*, has been granted indefinite leave of absence by the district commissioners.

PHYSICIANS LICENSED.—The following named physicians, having successfully passed the District examination, have been licensed to practice by the Board of Medical Supervisors: Drs. Jesse Lee Adams, Jr., John R. Atwell, George Kasper Baier, Wm. Mitchell Barnes, Levi C. Blake, Martha Clark Burritt, Wm. J. Bush, John A. Clark, Carl A. Clemons, Elmon A. A. Cook, Thomas Dowling, Jr., Wm. N. Fisher, A. F. Foy, Julia M. Green, Thomas A. Groover, Carl D. Haas, Stuart C. Johnson, Carl S. Keyser, Robert S. Lamb, W. R. Rives, Jr., Lewis Albert Walker, Charles S. White and Wm. E. Whitson.

ARMY APPOINTMENT.—Dr. William E. West of New York, resident physician at Columbia Hospital and late resident physician at the Central Dispensary and Emergency Hospital, has been appointed an Assistant-Surgeon, U. S. A., for duty at Porto Rico on the U. S. ship *Florida*.

WASHINGTON TRAINING SCHOOL FOR NURSES.—The Washington Training School for Nurses will hereafter be operated in conjunction with the Emergency and Alms House Hospitals. Congress has appropriated \$6,000 for a nurses' home to be established at the Alms House Hospital grounds. Application for admission to the school for free instruction will be received at either institution, or by Dr. H. L. E. Johnson, Dean.

CENTRAL DISPENSARY AND EMERGENCY HOSPITAL.—The hospital has recently suffered great loss in the death of Dr. George Byrd Harrison, a member of the Board of Trustees, and one of the consulting staff. Dr. Harrison formerly had charge of the Department of General Disease. The medical staff called a special meeting and adopted appropriate resolutions of regret. Mrs. Phebe Hurst has donated a large building and grounds opposite the hospital to be used as a nurses' home for the institution. The gift was made through Dr. Burnett, who is having the necessary alterations made, when it will be formally transferred. Congress appropriated \$2,000-

for necessary repairs to the hospital and the work is being pushed with dispatch. In order to prevent overcrowding and imposition on the hospital, the Board has agreed to charge \$15 a week to those able to pay for board. This is in line with the wishes of the Medical Association.

HEADQUARTERS FOR THE RED CROSS.—Dr. J. Ford Thompson has tendered the use of house 1310 G Street to the American National Red Cross Society as a headquarters for their committee. The offer has been accepted and the committee has raised the Red Cross flag over the building.

GIFT OF THE RED CROSS.—Surgeon-General Sternberg has acknowledged the receipt of \$5000 from the supply committee of the Red Cross Society, which he will distribute. He will send \$1000 to Colonel Forwood, chief surgeon at Montauk Port; \$1000 to Colonel Harvard at Santiago; \$1000 to Colonel Greenleaf, chief surgeon on General Miles' staff at Porto Rico; \$1000 to Lieutenant-Colonel Hoff, chief surgeon at Chickamauga; \$500 to Major Hale, in charge of the U. S. Hospital at Ft. Thomas, Ky.; \$500 to Major Fay, in charge of the U. S. Hospital at Ft. McPherson, Ga., all of which will be used for the purchase of delicacies for the sick and wounded soldiers who are arriving at these points.

ISOLATION HOSPITAL PLAN.—The district commissioners have appointed an additional architect to assist the inspector of buildings in the preparation of plans for the construction of an isolating building on the grounds of Providence Hospital for the reception of minor contagious diseases. The entire cost of the building is not to exceed \$25,000.

HOSPITAL FOR FOUNDLINGS.—The superintendent of the Washington Hospital for Foundlings has submitted the yearly report to the district commissioners. The average number of children cared for this year has been larger than any year since its organization in 1887. The total number in hospital June 30, 1898, was forty-six, and forty-four received during the year. Thirteen were adopted by outsiders, nine died and four were transferred to other institutions. Mal-nutrition caused the greatest number of deaths. The total receipts of the year were \$11,485.88; total expenditures, \$7449.48, leaving a balance of \$4036.40.

THE NEW MORGUE.—The coroner, Dr. Wm. P. Carr, reports that the new morgue for the District will shortly be completed. The morgue will not compare favorably with morgues of other large cities, but it will be a great improvement on the old shed in the rear of the station-house, previously known as the morgue. It is to be but a one-story building, with only two rooms, but will be fitted out with ice-boxes and other necessary paraphernalia to the extent of the parsimonious appropriation for that purpose.

GEORGETOWN UNIVERSITY HOSPITAL.—The Committee of Administration of the Georgetown University Hospital, consisting of Drs. J. T. Johnson, S. S. Adams, George T. Vaughn, Chas. Klineschmidt and Geo. M. Kober have announced, by circular, the formal opening of the hospital for the reception of patients. The free beds are for the benefit of indigent sick, but evidence of dependency must be furnished in accordance with the rules of the Medical Association of the District of Columbia before admission is granted. Seven rooms have been fitted up for the accommodation of pay patients, and the privilege of attending private patients in these rooms is extended to all members of the Medical Association and to surgeons of the Army and Navy and Marine Hospital service. The hospital will have in addition a well-equipped emergency and dispensary department.

Philadelphia.

WILL OF DR. PEPPER.—The will of the late Dr. Pepper was admitted to probate a few days ago. It was drawn up in February last and is very short, covering three typewritten pages. The actual value of the estate is unknown, personal property \$100,000, and real estate \$20,000, being only nominal items to

comply with regulations concerning the fees of the register. It is known that Dr. Pepper carried heavy life insurance, and it is the prevailing belief that the entire estate will approximate a million dollars. Four executors were chosen: his widow, Mrs. Frances Pepper; his eldest son, Dr. William Pepper; his nephew, George Wharton Pepper, and his brother-in-law, James B. Leonard. After the provision that his brain be given to the anthropometric society and his body be cremated, the other provisions concern the real estate and personal property to be divided between his wife and three sons.

DR. PEPPER'S SUCCESSOR.—While discussion of Dr. Pepper's successor at the University of Pennsylvania may not be with good grace, since the time of his death has been so short, yet there is some speculation going on regarding the one upon whose shoulders the mantle of the distinguished teacher and clinician will fall. It appears that there are several being mentioned for the chair, but matters have not progressed far enough to say with any reasonable certainty as to who it will be. Of those mentioned, the names of Dr. William Osler and Dr. James Tyson seem to be most prominent. It will be remembered that Dr. Osler once occupied the chair of clinical medicine in the University of Pennsylvania, but subsequently accepted the chair which he now holds at the Johns Hopkins. Dr. James Tyson succeeded Dr. Osler as professor of clinical medicine at the University, and as he has filled this chair for the past four years, therefore becomes the logical successor of Dr. Pepper. Dr. Tyson has been connected with the University almost since he was graduated in 1863, first as lecturer in microscopy (1868) and in chemistry (1870), and later professor of microscopy and physiology in the Pennsylvania College of Dental Surgery. In 1874 he became lecturer on pathologic anatomy, and in 1889 succeeded Dr. Osler in the chair of clinical medicine. It is a question whether or not Dr. Osler would be willing to give up his chair at the Johns Hopkins to accept the chair at the University of Pennsylvania. Provost Harrison is reported as saying: "The trustees will not meet until October, and it is impossible to say with any accuracy who will be chosen as Dr. Pepper's successor. I would not want to discuss the question now."

SICK SOLDIERS OF PENNSYLVANIA.—It is proposed to bring back all those patients now ill with typhoid fever and other diseases, to Philadelphia, where they may be placed in suitable hospitals. The University Hospital, Episcopal Hospital, Pennsylvania Hospital, German Hospital and St. Ayers Hospital, have tendered their beds free of charge for the treatment of these cases. To bring the cases home a complete hospital train has been fitted up by the Pennsylvania Railroad Company, consisting of eight coaches, of which five were fitted up as hospital cars with a capacity of 100 patients, two Pullmans, to be used a dining and sleeping car by the physicians and nurses. The train will be in charge of Drs. Carl Freese of the German Hospital; Henry Sykes of the Episcopal Hospital; George Pfroem of the Medico-Chirurgical Hospital, and Wilmer R. Batt of the City Council, with a full corps of nurses. The University of Pennsylvania claims priority over all others in tendering its services to the Government, Provost Harrison having written to Governor Hastings to that effect April 29.

YELLOW JACK AND PHILADELPHIA.—Aside from the precaution exercised by the city and State, the United States government is under existing laws taking precautions against the introduction of yellow fever into Philadelphia and other cities. A few days ago an inspecting party left this port on the "floating" quarantine station *Protector*, built for the purpose of preventing the entrance of yellow fever into this city. The *Protector* was taken to Fort Pond Bay, near Montauk Point, where it will remain under the charge of Dr. J. J. Kinyoun, bacteriologist of the Marine Hospital Service. It is the intention to destroy all germs of yellow fever by thoroughly disinfecting the baggage of every soldier coming into port, also to

cause a reasonable detention of the person before mingling with those who have not been in infected areas. The vessel is built of steel, 150 feet long, over 20 feet beam and without propelling machinery. The cost of building of the vessel, apparatus, etc., was about \$50,000.

PREVENTION OF TUBERCULOSIS.—Judging by an editorial which recently appeared in one of the lay papers here, the people are gradually learning that prevention is the best means of stamping out that disease. Frequently we hear it stated that tuberculosis is gradually becoming more prevalent in the larger cities, but this does not apply to Philadelphia. On the other hand, the statistics prove that deaths from that disease are gradually growing less. For instance, in 1892 deaths to 1000 persons living was 2.480; in 1895, 2.104, and in 1897, 1.966. This reduction in the number of deaths from tuberculosis in Philadelphia is attributed to the good work of the Pennsylvania Society for the Prevention of Tuberculosis, under the supervision of Dr. Flick, who located infected areas and infected houses throughout the city in 1892. The paper then speaks of ways of preventing the disease, such as through the inspection of food supplies, suppressing the habit of expectorating along the public highways, and taking the necessary precaution in those houses infected by tuberculosis. As a further method of suppressing the disease, it is recommended that a State sanitarium be built where these cases might be treated under the care of those most competent to render effectual aid.

PTOMAIN POISONING.—Two families are seriously ill with symptoms of ptomain poisoning derived from ham. One, the Cortledge family, is composed of the father, mother and two-year-old child; the other of two boys, aged 12 and 3 years, respectively, and a girl, aged 21 months. On the 15th both families ate boiled ham for supper (bought at the same store) and at 11 o'clock Mr. Cortledge and child were seized with violent abdominal pains, accompanied by vomiting. The mother was only slightly affected. It was subsequently learned that the other family were similarly affected, and two physicians pronounced the cases ptomain poisoning. The ham had been boiled by the manufacturer in this city, but those who had prepared the food for market could not be found. Samples of the food are being examined.

MORTALITY REPORT.—For the week ending at 12 o'clock, August 15, 443 deaths had been reported to the Board of Health. This shows a decrease of 41 over the previous week and of 37 over the number for the corresponding period of last year. Of the total number of deaths, 164 occurred in children under five years of age. The principal causes of death were: Nephritis, 18; cancer, 14; cholera infantum, 57; phthisis, 52; dysentery, 4; marasmus, 24; paralysis, 8; suicide, 2; whooping cough, 3; sunstroke, 9; heart disease, 20.

INFECTIOUS DISEASES.—This week: Diphtheria, 16 deaths and 45 cases; scarlet fever, 1 death and 10 cases; typhoid fever, 78 cases and 8 deaths. Last week: Diphtheria, 2 deaths and 49 cases; scarlet fever, 25 cases; typhoid fever, 13 deaths and 60 cases.

RESULT OF EXAMINATIONS.—The report of the examinations of the last meeting of the State Medical Board has just been published and the following results are tabulated:

	No. examined.	No. rejected.	Per cent. of rejections.	General average.
University of Pennsylvania	93	1	01.0	83.63
Medico-Chir. Col., Philadelphia	76	8	10.5	78.81
Woman's Medical Col., Phila.	26	1	03.9	78.68
Physicians and Surgeons, Baltimore	2	1	50.0	76.71
Jefferson Medical College	20	5	25.0	74.75
Western Pennsylvania	21	8	38.1	72.39
Miscellaneous	53	17	32.1	75.61
Total	316	47	14.9	78.77

The honors in this examination were held by the University of Pennsylvania and the Medico-Chirurgical College of Philadelphia, the University leading, as it generally does. The Medico-Chirurgical College, however, made a good average for the hospitals here and captured one-half of the positions on the resident staff of the Philadelphia Hospital.

INFECTED DURING A SURGICAL OPERATION.—Dr. Emil Dippe, chief resident surgeon at St. Timothy's Hospital, while assisting in an abdominal operation on July 4, inoculated himself with infected material, near the nail on the left hand. A

localized abscess formed but was relieved by an operation. Subsequently another abscess developed in the left axilla and the Doctor can only be relieved by another operation.

ALMSHOUSE MAY BE ENLARGED.—The Board of Charities has recommended that councils appropriate \$60,000 to be expended in repairing and otherwise making room for the care of patients now in this institution. At present there 1355 insane patients being treated in the buildings, which are greatly overcrowded.

ROUGH RIDERS AT THE UNIVERSITY HOSPITAL.—Alfred Roey, a Cuban, Percy Geyer of Colorado and Joseph Adkins of Colorado, were taken ill on their way from Tampa to Montauk Point, the quarantine station, recently, and were transferred to the University Hospital.

WILL INSPECT ARMY CAMPS.—Dr. E. O. Shakespeare of Philadelphia, member of the Sanitation Committee of the National Relief, has been commissioned to head a council, whose duty it shall be to inspect the various United States Army Camps and to better matters where unsanitary conditions are found. The National Relief Association recently issued an earnest appeal for funds to support its work, both in the States and in the field, with very good results. It is stated that this special board has been created to render void the necessity of red-tape methods at the different departments at Washington, and that matters will receive attention with much greater dispatch. Remembering that typhoid fever and preventable diseases have been on the increase from the time that soldiers were first put into camps, it seems just a little strange that some one was not sent to these places long ago; but as health matters are usually those which receive attention last, and since the war is over, these things may be now considered. When unsanitary conditions are found, Dr. Shakespeare will at once telegraph to Washington, and all measures likely to bring about disease will be corrected immediately.

PHILADELPHIA SOMEWHAT UNCLEAN.—During the recent inspection for any latent case of yellow fever which might have crept in unawares, certain districts along the Delaware were found in unsanitary condition. Chief Nuisance Inspector Kennedy presented his report to the Board of health a few days ago, stating that 3673 premises had been visited and rigorously inspected and that 704 nuisances were discovered.

EXPERT TESTIMONY.—Dr. Charles K. Mills of the University of Pennsylvania has been called to Lancaster, Pa., to give expert testimony in the Wireback murder trial.

PHILADELPHIA POLYCLINIC.—The fifteenth annual report of this institution shows that during the year 92,564 visits were made to the dispensary and 634 operations were performed under ether. Miscellaneous contributions during the year amounted to \$7,500 and a State appropriation of \$2,500 was received. The operating expenses were \$41,824.23; receipts \$41,152.88. To this must be added \$10,725.46, being the amount of floating indebtedness on Jan. 1, 1897, which makes the total floating indebtedness of the institution on Dec. 31, 1897, \$11,406.81.

THE PUBLIC SERVICE.

Memoranda Relating to Operations of the Medical Department, U.S.A.

MEDICAL OFFICERS.—The number of medical officers allowed by law is inadequate in times of peace. The total number allowed is one hundred and ninety-two. There are at present thirteen vacancies. The administration of the Surgeon-General's Office and the Army Medical Museum requires six. Eleven are on duty at medical supply depots and as chief surgeons of military departments. One is at the Soldier's Home; fifty-six are at general hospitals, on hospital ships, and at garrisoned posts. Four have been disabled during the war by sickness. Five are on duty as chief surgeons of army corps. This leaves ninety-six medical officers available for duty with troops in the field. Of these, thirty-five have been appointed brigade surgeons of volunteers, and are distributed among the various army corps.

This deficiency in regular medical officers has made it necessary to employ nearly four hundred contract surgeons, and more are being employed every day. Most of these doctors from civil life are doing good service, and many of them are thoroughly well-equipped physicians and surgeons, with ample hospital experience; but it has been impossible to make a careful selection, owing to the great pressure of business in the Surgeon-General's Office, and the urgency has been so great that it has not been practicable to have examining boards to pass upon their qualifications.

In addition to this, there have been appointed by the President, eight brigade surgeons with the rank of lieutenant-colonel, twenty-four division surgeons with the rank of major,

and sixty-five brigade surgeons; also three medical officers for each of the regiments of U. S. Infantry, Cavalry and Engineers. All volunteer regiments have three medical officers appointed by Governors of States.

General hospitals have been established at Key West, Fla., with a capacity of 755 beds; at Fort McPherson, Ga., 1050; Fort Thomas, Ky., 432; Chickamauga Park (Leiter Hospital), 255; Fortress Monroe, Va., 535; Fort Myer, Va., 308. In addition to this, several hundred sick and wounded soldiers have been placed in the Marine Hospital on Staten Island and in civil hospitals in New York and Brooklyn; also nearly two hundred in the civil hospitals in Charleston, and a smaller number in civil hospitals in various parts of the country.

The Hospital Train, which was equipped for service June 22, and consists of ten tourist sleepers and a dining car, has made repeated trips from Camp Thomas, Tampa and Fernandina, with sick, to the general hospitals at Fort McPherson and Fort Thomas, and has proved to be most useful.

The Hospital Ship *Relief* was purchased May 18, but owing to delays in preparing her for service, did not sail from New York until July 2. Four days later she arrived at Siboney with an ample supply of medical stores of all kinds and with sixteen doctors. She returned to New York with a load of wounded and was then dispatched to Porto Rico. She is now returning to New York with 260 sick and wounded soldiers.

The Hospital Ship *Olivette* went with the Fifth Army Corps from Tampa, Fla., to Santiago and brought a load of wounded from that port to New York. She returned to Santiago with supplies and is now en route to New York with 200 patients.

MEDICAL SUPPLIES.—When the troops were originally ordered from their respective posts into the field each regiment was required to take with it medical and surgical chests, litters and field supplies for three months. Afterward, medical supplies in ample quantities of all kinds were sent to Tampa for the Fifth Army Corps, about to sail for Cuba, and supplies have subsequently been sent to the several camps that were formed, wants being anticipated as far as possible and requisitions approved promptly on receipt.

Supplies for the army have been furnished from three medical supply depots: New York, St. Louis and San Francisco, the latter supplying very largely, by purchases on the Pacific Coast, the troops that went to Manila. St. Louis depot supplied the camps and regiments in the Mississippi Valley and the West; and the New York depot the camps and expeditions fitted out from the Atlantic Coast.

In addition to general medical supplies in great variety, 1204 medical and surgical chests have been issued, the surgical chests containing surgical instruments and dressings especially designed for the relief of wounded on the battlefield.

The extent of the demands upon the medical supply depots is indicated by the following figures, showing the issue of some of the more important articles.

First aid packets	No.	272,000
Hospital corps pouches	"	5,797
Orderly pouches	"	509
Pocket cases	"	952
Surgeon's field cases	"	389
Field operating cases	"	328
Medical and surgical chests	"	1,204
Litters	"	2,250
Litter slings	"	7,600
Cots and bedsteads, with bedding	"	18,185
Blankets, gray	"	23,950
Field desks	"	440
Quinin pills	"	7,300,000
Chloroform and ether	bottls.	13,220
Gauze, sublimated, 1 meter pkgs.	Pkgs.	100,000
Gauze, bandages, 3 sizes	No.	331,776

SICK AND WOUNDED.—At the present time, August 15, we have a full record of 40,620 cases of sickness and wounds that occurred among a mean strength of 154,028 men, during the months of May, June and July. As the average of the 3 months probably 6 per cent. of the troops were constantly sick. Reports from commands not yet represented in the statistics are expected daily.

HOSPITALS CORPS.—Immediately at the outbreak of the war the Hospital Corps consisted of one hundred hospital stewards, one hundred and three acting hospital stewards and five hundred and twenty privates, making a total of seven hundred and twenty-three. The larger part of this number was ordered with the troops that left their respective stations to the camps of concentration and accompanied the regular regiments in the 5th Army Corps to Cuba, the smaller part being left behind at the various Army Posts, they being just enough to take care of the medical property.

Enlistments were at once ordered throughout the country of suitable men for the Hospital Corps, special attention being paid to enlisting nurses, pharmacists, cooks, drivers, mechanics, etc. A good many medical students and young physicians were also accepted.

By means of enlistments and afterward by transfers from volunteer regiments to the Hospital Corps a large number of men were obtained, and today there are in service by actual count five thousand and eighty-four. Probably a thousand are in service whose enlistment and transfer is not yet reported.

In addition to the members of the Hospital Corps enlisted for the purpose of taking care of our sick and wounded, we have employed 141 male nurses and 386 female nurses under contract.

CIRCULAR NO. 6.—

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE,
WASHINGTON, Aug. 12, 1898.

Chief surgeons of army corps, of divisions and of smaller independent commands are expected to make timely requisition for medical supplies. It must be remembered that some delay is often unavoidable in putting up supplies at the supply depots and in their transportation to the point at which they are needed. In an unexpected emergency telegraphic requisition must be made and supplies will be sent by express; but it must be remembered that this mode of transportation is very expensive and that failure to make requisition in advance of immediate needs entails unnecessary expense upon the Government. Division and field hospitals in which typhoid fever and other serious cases are treated should be liberally supplied with all articles necessary for the treatment and comfort of the sick. The field supply table applies only to mobile commands and division hospitals to accompany them on short notice.

GEO. M. STERNBERG,
Surgeon-General, U. S. Army.

The Journal of the American Medical Association

VOL. XXXI.

CHICAGO, ILLINOIS, SEPTEMBER 3, 1898.

No. 10.

ADDRESSES.

THE INFLUENCE OF AGE, SEX AND RACE IN SURGICAL AFFECTIONS.

Address of the Chairman of the Section on Surgery and Anatomy, at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY WM. L. RODMAN, M.D.

LOUISVILLE, KY.

Gentlemen of the Section:—Allow me first to express my grateful appreciation for the honor conferred upon me at the Semi-Centennial Meeting. To be chosen as Chairman of this, the largest Section of the ASSOCIATION, is indeed an honor any one should esteem highly.

I have endeavored, with the aid of the distinguished Secretary, Dr. Parkhill, to present to you as attractive a program as has ever been offered to this or any other Section in former years. Indeed, too much credit can not be given our Secretary for his indefatigable labors and their fruitful results. We regret that his obligations to our country, now resounding from end to end with stern alarms, deprive us of his companionship and help on this occasion, to which he has looked forward with such keen pleasure, and for the success of which he is so largely responsible. I am sure that I voice the sentiments of every member of the Section, when I thank him for his work in our behalf, and bespeak for him a safe return to Denver, where his professional worth and surgical skill have long been recognized as second to none. Our loss is the country's gain, and we might well wish that all of our countrymen needing surgical attention in the pending war with Spain, may fall into hands as competent and deft as the Surgeon of Colorado's Volunteer Corps.

We also wish to express our gratitude to Dr. Powers, the Acting Secretary, who on short notice assumed the work and gave to it most intelligent and conscientious attention.

In offering for your consideration the customary Chairman's Address, I have chosen for my subject "The Influence of Age, Sex and Race in Surgical Affections." Time limits will prevent consideration of all diseases having a bearing upon the subject, and your attention will, therefore, be asked to some affections seeming to have a pointed claim to our notice.

The treatment of racial differences has been almost necessarily limited to the white and black races of North America, as but few of the many army and navy surgeons to whom I have written for data gathered by them in their various assignments, have been able to reply at satisfactory length on account of the exacting demands of the past three months.

The diseases of the negro possess an abiding interest to those of us living in the South, called upon as we are daily to give him professional succor in private, hospital and dispensary practice. Although much

that is of value has been written of his immunities and susceptibilities to disease, it has occurred to me that the last word has not been spoken, due more to the changes in the negro himself than to inaccurate observations on the part of medical writers of the past and present.

To the careful student who reviews the literature of the subject, there is no escape from the conclusion that the negro as we now find him, with changed environments, habits and associations, is a different being from what he was in antebellum days. He came to America three hundred years ago with certain immunities and susceptibilities to disease, which were so conspicuous as to be noted by all trustworthy observers. A few of the immunities he hitherto enjoyed have been maintained, more have been lost in part, others wholly exhausted, and to some few diseases he shows not only the same liability as the Caucasian, but even exceeds him in vulnerability, to-wit: local tuberculosis of glands, skin and bones. The original susceptibilities of the negro seem to have abided with him, and to have undergone less change, he still being as obnoxious to fibroid and other benign neoplasms as he has ever been, as well as to keloid, elephantiasis and tetanus. Not only is the race manifesting an increasing tendency to disease of all kinds, but statistics of every Southern hospital will prove them to be less resistant and to show a larger mortality, both in medical and surgical affections (operative and non-operative cases), than the Caucasian. The full-blood is less resistant to begin with, and the mulatto inherits the weaknesses of both races, the strength of neither, and begins life with the heaviest of handicaps. Therefore, it is not surprising to the observant to occasionally hear such authorities as Hunter McGuire, D. W. Yandell, and other thoughtful practitioners of large and long experience with this race, say that the African will in time become as extinct in this country as the bison and the North American Indian. It is clearly foreshadowed, that he can not maintain the struggle for life with a race his superior in every respect, in a climate to which he is ill-suited at best.

MALIGNANT DISEASE.

All early writers testified to the immunity of the African, in both his native and adopted country, to malignant disease. It can not be doubted, I think, that as a race, cancer was most rare with them up to fifty years ago. These early writings have too much influenced practitioners of this generation, however, and many reason that cancer is still rare with negroes, because such was undoubtedly the case a few generations ago.

Malignant disease (both sarcoma and carcinoma) is certainly increasing in frequency in the black with even greater ratio than in the white race. From a condition of practical immunity they have become nearly as liable to malignant disease of some organs

as the white, quite as much so to that of the mammary gland and the seemingly more obnoxious cancer of the uterus. The records of the City Hospital and Health Department of Louisville for the past thirty years are in line with the statements and statistical data of Billings and Matas, and emphasize especially the frequency of cancer of the uterus in negroes. It would be interesting to know what per cent. of the cases were in full-bloods; but it is impossible to ascertain this, as no distinction is made in our reports between full-bloods and mulattoes. Nor is it possible to determine with reasonable accuracy the relative number of cases of sarcoma and carcinoma, and therefore, no attempt is made to do so.

It is safe to say, however, that the negro is relatively somewhat more prone to sarcoma than cancer. As has been stated, the mammary gland suffers as often in the black as in the Caucasian, the uterus more so. Now it would appear *à priori*, that the negro, almost universally affected as he is with phimosis, should show a special susceptibility to cancer of the penis; yet I have never seen such a case, nor do the records of our city hospital indicate that one has been treated there in thirty years. Of 207 deaths from cancer in negroes reported to the Louisville Health Department in thirty years, none have been entered as cancer of the penis.

According to the eleventh census (just issued), malignant disease occurs in every 100,000 living inhabitants:

Whites	53.93
Negroes	36.65
North American Indians.	5.31
Chinese a little less liable than Indians.	

To every 1000 deaths from known causes in the United States in persons over forty-five years of age, there were due to cancer and tumor:

Whites	62.86
Negroes.	29.81
North American Indians	14.49
Chinese.	12.99

In this country, as in England, cancer is alarmingly on the increase. Both races show a marked increment of gain, and so far as cancers in general are concerned, the increase has been about the same in the two races, as will be shown by the table giving every death from cancer in Louisville for thirty years. These records have been gone over by my assistant, and are, I am sure, reliable, as he has devoted weeks to the work. It will be seen that the number of cases has doubled each decennium.

CANCER OF ALL PARTS.

1868 to 1878—total number deaths 244; white 205; colored 39.
1878 to 1888—total number deaths 484; white 411; colored 73.
1888 to 1898—total number deaths 892; white 797; colored 95.
Total number deaths for thirty years 1620; white 1413; colored 207.

There have been 161 cancerous patients in the Louisville City Hospital during the past twenty years (1878 to 1898). The records of the decennium from 1868 to 1878 are incomplete and are therefore excluded. Of cases admitted there were 118 white and 43 colored.

1878 to 1888—total number cases admitted 63; white 47; colored 16.
1888 to 1898—total number cases admitted 98; white 71; colored 27.
1878 to 1898—total number cases admitted 161; white 118; colored 43.

These statistics agree fully with those of Matas, drawn from the service of the Charity Hospital in New Orleans, and show that malignant disease, instead of being uncommon in the negro, is as often encountered in him in Southern hospitals as it is in the whites.

Of 1620 deaths from malignant disease reported to

the Louisville health office, 1413 were whites and 207 colored, or about one-eighth of the total number; the normal proportion of colored population to white in Louisville is one to four, which indicates the mortality in the colored population to be 50 per cent. of what it is in the white for cancers in all situations. This I believe to be nearer the truth than the smaller hospital series indicates, as it deals with the entire population of the city, and is moreover nearly in accord with Billings' eleventh census statistics (death rate 53.93 to 100,000 living white inhabitants and 36.65 colored). Further, these represent deaths, and are not open to the objections clinical diagnoses may be.

The discrepancy between the statistics of the hospital and health office are apparent and not real, for, while the hospital shows the colored race to suffer as often as the white, it should be remembered that the improvidence and indigence of this race force them into the city hospital twice as frequently as the more favored whites. The normal hospital proportion of colored to white is just double that shown by the city at large; hence the two reports are in perfect harmony and show the negro to suffer one-half as often from cancers in general as the whites.

Mammary gland.—Far from being uncommon, as many practitioners believe, malignant disease of the mammary gland is as frequent in the black as the white. Personally, I have seen five cases, and know from a colleague that two others were recently in the city hospital. The first case of cancer of the breast I ever saw was in a negress about forty years of age, as black as a crow's wing. She died from recurrence after operation, at the usual time and in the usual way, confirming the clinical diagnosis. In all the others the clinical diagnosis was confirmed by the microscope and by the death of each from recurrence.

There were 889 cases of cancer of the breast reported in the eleventh census; 811 females, 28 males. One occurred under 15 years of age; 163 between 15 and 45; 670 at and over 45. Rate of death to 100,000 inhabitants: females, 8.23; males, 0.29; age 45 to 65, 30.08; 65 and over, 50. Death rate practically same in white (4.27) and colored (4.19).

The records of the Louisville city hospital for the past twenty years show that three-fifths of the cases were whites and two-fifths colored, though the latter represent but one-third of the hospital population. Our health office shows that there were fifty-eight deaths from mammary cancer in the past thirty years. Of this number fifty were white and eight colored.

1868 to 1878—total number cases	mammary cancer 14; white 14; colored 0.
1878 to 1888—total number cases	mammary cancer 17; white 15; colored 2.
1888 to 1898—total number cases	mammary cancer 27; white 21; colored 6.
1868 to 1898	58; white 50; colored 8.

Undoubtedly there have been a larger number of deaths from cancer of the breast, but many have doubtless been entered as "cancer" without giving situation. Small as this series is, it emphasizes the increase of cancer in the negro, especially, and shows that as a race they suffered more frequently than the white during the past ten years.

Cancer of uterus.—The eleventh census shows cancer of the uterus to be far more common in the colored race. There were 1472 cases reported and the death rate was 24.94 in the negro and 14.41, or but little more than half the number in white women. Table shows death rate per 100,000 during census period at all ages:

	All ages.	15 to 45 years.	45 to 65 years.	65 years and over.
Total	14.93	9.32	54.01	45.91
White	14.41	8.79	52.29	44.36
Native born	10.98	7.51	51.71	43.71
Foreign born	22.92	11.98	50.79	41.77
Colored	24.94	18.82	94.59	88.36

The death rate is very much higher in the colored race for all ages.

Both the Louisville city hospital and health office statistics show cancer of the uterus to be more common in the black race. From 1878 to 1898 there were 31 cases of cancer of the uterus in the city hospital; of these 23 were white and 8 colored (normal proportion of colored to white in hospital 1 to 3), showing relatively a greater number of cases in the black race:

1878 to 1898—total cases 13; white 12; colored 1.
1888 to 1898—total cases 18; white 11; colored 7.
1878 to 1898—total cases 31; white 23; colored 8.

From 1868 to 1898 there were 272 deaths from cancer of the uterus reported to the health office of Louisville; of this number 216 were white and 56 colored. It shows a per cent. against the negro—our normal population being 1 to 4. Total number deaths from carcinoma uteri in Louisville from:

1868 to 1898—272; white 216, colored 56.
1868 to 1878—39; white 29, colored 10.
1878 to 1888—190; white 74, colored 27.
1888 to 1898—133; white 113, colored 20.

I would be glad to pursue the subject of regional liability in the two races further, but it is impossible at this time; suffice it to say that liable as the mammary gland and uterus of the negro are to malignant disease, certain other regions which one would expect to suffer often do so infrequently. I have never seen cancer of the penis, larynx or tongue in a negro, while rectal cancers are common.

Cancer is rare in Indians, and when it does occur, so I am informed, attacks the breast and uterus. Great smokers as they are, their immunity to cancer of the lips has been remarked upon by a number of army surgeons who have written me. Cancer is rare in all savage races, and is pre-eminently an affection which increases in frequency with a higher state of civilization. Dark-skinned races suffer less than the fair.

Age and sex.—Women are twice as liable to malignant tumors on account of their proneness to disease of the uterus and mammary gland, which embrace one-half of the cases in the female sex. Snow's statistics, gathered from the Cancer Hospital in London, and those of W. Roger Williams recently published, clearly attest woman's double liability. The sexes are upon a parity up to the fifth quinquennium, when the difference between them becomes striking. From 25 to 55 the female is nearly three times as liable to malignant disease, and from 55 to 90 is almost twice as obnoxious. Gusserow, who analyzed 3385 cases of uterine cancer, found only two to have occurred prior to 20; while of Gross' series of 1622 mammary cancers the youngest was 21, a ready explanation of the heavy tribute woman pays to malignant disease during the activity and devolution of her sexual organs.

Age.—Infancy and childhood are practically exempt from epithelial malignant neoplasms (cancer), the youngest case on record being one of cylindroma of the rectum in a girl aged 11 (Stern). Cancer being rare prior to 30, then gets to be more common, is ever thereafter more liable to occur with each suc-

ceeding year, and has been reported by Sutton at 102. Practically all tumors of infancy and early childhood are sarcomata, they being nearly as exempt from benign neoplasms as they are to true cancers. Sarcomas of the eye, kidney, testis and prostate are common in infancy, and may be in many instances congenital.

Duzan analyzed 182 cases of sarcoma in infancy, and found 70 of the eye, 45 of the kidney, 11 of the testicle, 8 of the prostate; while the bones, tongue, abdomen and brain were affected 5 times each; lung and dura mater 4 times; pancreas 3; liver, tonsil and rectum 2 each and stomach 1.

During the second decennium the long bones and maxillae are the usual sites of sarcoma. The long bones still suffer in the third, and in the fourth decennium some of the long bones, as the humerus, and the mammary gland and testicle exhibit their greatest tendency to sarcomatous change. After forty, sarcoma is rather uncommon until sixty, when it again becomes frequent. Like cancer, it is common as a senescent change, but unlike it, shows its greatest destructiveness in infancy and early childhood.

The following tables are by W. Roger Williams, on "The Malignant Tumors of Infancy, Childhood and Youth," the *Lancet*, London, May 1, 1898:

TABLE 1. Showing the deaths due to malignant disease at different age periods:

Period.	All ages.	Under 1 year.	1-2.	2-3.	3-4.	4-5.	Total under 5 years.			
Males	57,454	8	6	6	6	5	31			
Females	10,489	7	6	6	6	6	31			
	5-10	10-15	15-20	20-25	25-35	35-45	45-55	55-65	65-75	75-85
Males	18	18	33	50	145	426	1095	1727	1555	591
Females	15	18	25	41	321	1313	2464	2922	2330	910

Over 85, males, 65, females, 101. Total both sexes, 16,243.

TABLE 2. Showing the number of deaths from malignant disease in early life per million persons living at each age period:

Age periods.	Under 5.	5-10.	10-15.	15-20.	20-25.	All ages.
1861-70	13	7	7	7	17	384
1871-80	12	7	7	15	27	464
1881-90	20	10	11	20	35	539

BENIGN NEOPLASMS.

As a class the mesoblastic benign neoplasms are more common with the negro, he being exceptionally obnoxious to fibroma, lipoma and keloid. Molluscum fibrosum, which I am not disposed to question is more frequent in the negro, is, I am sure, a more common affection in the whites of this and even more Northern latitudes than authorities admit. Many speak of it as an affection almost peculiar to the black races of the tropics, yet I have in my own practice seen three most beautiful instances of this disease in white males, all past forty, within the last four months. I have seen the disease more often in the white than the black. Keloid is also, I take it, more common in the white race than many believe, though it is certainly many times less frequent than in the negro. I have seen a number of typical keloids supervening upon vaccination scars, on the lobule of the ear after the piercing, and upon cicatrices variously situated, in the white race. I agree perfectly with Tiffany that operation does no good in young subjects, and that there is in elderly persons afflicted with keloid a spontaneous tendency to undergo resolution. There is no disproportion between the sexes in their liability to benign tumors.

Age: As has been intimated, the very young are practically exempt from benign neoplasms. The first decennium suffers rarely, and then usually from congenital angiomas and lymphangiomas.

TUBERCULOSIS OF BONES, JOINTS, SEROUS MEMBRANES AND GLANDS.

Pulmonary consumption, which was practically

unknown to the Africans and Indians of North America, several generations ago, has become their deadliest foe, and is fast decimating their ranks. It is more than twice as common in the African as the white, and still more prevalent with the Indian, the latter race suffering directly in proportion as they give up their tepee life and live in poorly ventilated buildings. Therefore, it is not surprising that local tuberculosis of bones, joints, lymphatic glands and serous membranes should show the same proportion of cases in the three races.

I am informed by reliable observers in the Medical Corps of the Army and Indian Departments, that an enormous per cent. of Indian boys and girls develop one or more varieties of surgical tuberculosis when they give up their outdoor life for the schoolroom. Tuberculosis in all of its manifestations has increased with the Mexicans in the same ratio as with the Indians.

Age has a distinct influence, and a majority of such cases occur in the first decennium, about one-fourth in the second, and the remainder after 20. The two sexes are equally obnoxious.

VARICOCELE.

This disease is closely associated with the evolution of sexual apparatus, and is, therefore, largely encountered in adolescence. In my own series of 215 operative cases, and many others not treated, I have never found it to begin before puberty, and rarely after 30. The immense preponderance of cases will be met with in the decennium from 15 to 25. Occurring, as it generally does, in youths who have not begun a sexual life, it is, as a rule, cured by marriage, unless of long standing and accompanied with atrophy of the testicle. While relatively rare in married men, I have operated within the last year upon four such cases in men aged 24, 30, 35 and 57 years respectively, the last being older than any other case in my series; in fact, his was the only instance of the disease I have seen past 40. He was a frail man, doing heavy lifting in his occupation as ship carpenter. The pampiniform plexus was greatly enlarged in this case, and the pain in the cord and back, and the dyspeptic symptoms were so pronounced that he was sent to me from Indiana for operation. He was promptly cured, and I have never seen a quicker and more decided improvement in one's general health, follow any surgical procedure. Negroes are practically immune to varicocele. It has been frequently observed that this race enjoys a relative immunity to varices in general. Varicose veins of the legs and hemorrhoids are noticeably less common in the negro, still a number of such cases have come under my observation. I have for fifteen years been looking for a varicocele in the negro, and my chief of clinic has been instructed to examine all males coming to our clinic, and has done so with negative result. In an analysis of more than 600 cases treated and operated upon by Louisville surgeons, not a single case has been seen in the negro, and only one encountered in a mulatto. I have taken great pains to see each of the clinical teachers and their assistants, and the records of the four large dispensary services of Louisville do not furnish a single case of varicocele, notwithstanding the fact that nine-tenths of our patients are negroes. Correspondence with surgeons and clinical teachers of other cities has almost invariably been followed by the statement, "Have not seen varicocele in negroes."

Prof. J. William White of Philadelphia, recently told me that in several hundred operations he had done for varicocele, none were negroes. Horwitz of Philadelphia, in 278 cases, has seen but a single instance, and that in a mulatto. Kirby of Philadelphia has not seen it in the negro. Tiffany of Baltimore, has had but one case and that in a bright mulatto. Prof. John P. Bryson of St. Louis writes me as follows: "We have failed to elicit, either from private practice or from clinics of the St. Louis Medical College or the St. Louis Hospital, a single case of prostatic hypertrophy or of varicocele occurring in the full-blooded negro. While, as you say, the negro population of St. Louis is not large, it seems unlikely that these conditions should exist to any but the rarest degree without some of them appearing at one or other of the two above named clinics. I have had abundant evidence of the prevalence of tubercular affections of both prostate and testis in the full black, but of hypertrophy of the former or of varicocele, I have no record or memory. The question is an interesting one, and may shed, on investigation, some light upon the obscure subject of the etiology."

Professor Hunter McGuire of Richmond, Virginia, writes me as follows: "I have never seen a case of varicocele in the full-blooded negro. I do not remember to have seen one in a mulatto."

Dr. F. C. Leber of Louisville writes: "Varicocele is rare in the negro. I can speak decidedly in regard to this, since in the four years during which I was President of the United States Board of Examiners of Pensioners in this city, I can not recall a single instance of this disease, while the cases in which pensions were granted to white veterans for this affection were quite numerous, as the records show."

Captain and Assistant Surgeon William L. Kneeder, United States Army, writes: "I have never seen a well-marked case in the negro. I served three years with colored regiments and examined many negro recruits."

Lydston of Chicago has seen "one case of moderate varicocele in a mulatto."

Bull, Wyeth and Coley of New York tell me that they have never seen varicocele in the negro.

Therefore, I take it, I am justified in assuming that the full-blooded negro is practically immune, and that mulattoes have varicocele most rarely. No one, so far as I know, has investigated this subject before, but it does seem to me that the evidence here presented is weighty. There are, I think, good reasons anatomically and physiologically for this marked immunity. Anatomically the testicles do not hang so low as in the white; are not so large, though the penis is larger, and the scrotum is close fitting and less lax than in the white man. In the negro the condition is much like the scrotum of the dog. Physiologically the negro begins his sexual life at puberty, and does not know what it is to be continent any time thereafter. Dissections which I have made and caused to be done have failed to show any difference in the veins of the negro from the white.

The usual causes of varicocele given in text-books and other literature fail to explain this striking immunity of the negro. I am satisfied that the better mechanical support given his veins, together with his lascivious life, furnish the best explanation. I also believe that the reason for this disease always affecting the left pampiniform plexus of veins is mostly due to the fact that the left testicle is larger, heavier and

more dependent than the right. This in conjunction with the fact that the spermatic veins empty at a right angle into the left renal instead of at an acute angle into the vena cava as upon the right side, and the absence of a valve upon the left side, which was shown by Brinton to exist upon the right, offer a perfectly satisfactory reason as to the left-sidedness of this disease, entailing as it must a sluggishness of the venous circulation upon this side. I do not believe that it ever occurs upon the right side unless preceded by a larger varicosity upon the left. In my 215 operations for varicocele I have encountered it as a bilateral condition in two cases, and in each the trouble was primary and much greater upon the left side. In only one of these cases did I operate upon both sides. In the second case the varix upon the right side promptly subsided after operating upon the left.

Several army surgeons to whom I have written making inquiry if varicocele was common among the North American Indians, have replied always in the negative. It must be, from the information I have at hand, at least rare, if it occurs at all, with the Crow, Arapahoe, Cheyenne, Sioux, Apache and Comanche Indians.

ENLARGED PROSTATE.

My own experience leads me to believe that enlargement of the prostate as a senescent change is common enough in the white after 50, but rarely seen in the negro. Every surgeon to whom I have written expresses the same opinion, many stating that they have never seen it in the full black. Prof. Hunter McGuire writes me as follows: "As much as I have had to do with this subject and as much as I have written about it, I never saw a case of chronic hypertrophy of the prostate gland in a pure negro; I see it very often in the mulatto and mixed breeds." Dr. F. C. Leber, who was president of the Louisville Board of Examiners of Pensioners, says that in his four years' service no case of enlarged prostate presented for examination in the negro. He has not seen it in private or hospital practice in thirty-seven years' experience. Prof. John P. Bryson of St. Louis writes that while he often sees tuberculosis of the prostate and testicle in the negro, he has never seen a single case of prostatic hypertrophy, nor do the records of the college and hospitals of St. Louis with which he is connected show a single instance of this affection. Profs. F. W. Samuel and H. H. Grant of Louisville, both surgical teachers and busy men, have never seen enlarged prostate in the negro, notwithstanding the fact that our negro population is one to four and our clinics are made up almost entirely from the negro population. Other Louisville surgeons, as Bloom, Roberts, Vance, Cartledge, Orendorf and Blue, have all expressed the opinion to me and have written that enlarged prostate in the negro is very rarely encountered. I have seen one case in a negro past 50 in twenty years' experience. My distinguished friend, Prof. P. S. Conner of Cincinnati, writes me that "enlarged prostate is infrequently found in blacks."

The records of the Louisville City Hospital for the past ten years have been most carefully examined, and there has not been a single case in the negro. I therefore agree with Matas that chronic enlargement of the prostate gland is a rare disease in hospital practice in Louisville, as it is in New Orleans, but can not

agree with him that it is relatively nearly twice as common in the black race. Age has a most important bearing upon enlarged prostate, and it is practically never seen before middle life. It is said by most authors that about one-third of all males past middle life are subject to some enlargement of the prostate; in only about one-tenth of these, however, is the enlargement of such a nature as to be of pathologic import. I am sure that I have never seen enlarged prostate, not clearly due to malignant disease, prior to 50, and few cases under 60. White and Martin state that prostatic enlargement occurs as a rule in men who have passed the age of 55, and that "on the basis of extensive tabulations it is, however, apparent that enlargement of the prostate begins only exceptionally under the age of 50, or after that of 70."

Since writing the above a letter has been received from Prof. H. H. Mudd saying that his case of supposed hypertrophy of the prostate in a negro aged 27, proved to be malignant. This case has been often quoted, and I am glad to have an authentic statement from Dr. Mudd. In his letter he says: "I have never seen a pure case of hypertrophy of the prostate in the negro. I reported two cases at one time; one a pure case of hypertrophy in a white child, aged 13 months, and another, a full-blooded negro with very large prostate which proved to be malignant. The prostate of this case was a hard, firm, malignant growth of the size of the two fists. I will look up my reports and see if I can give you a description of the pathologic conditions found by examination under the microscope."

A letter of more recent date says that the enlargement of prostate filled the pelvis and was found to be alveolar sarcoma. This disposes of a hitherto puzzling and much quoted case.

GALL-STONES.

That gall-stones practically never occur during the first decade of life, and but rarely in the second, I am now assured after an extensive search of the literature of the subject and personal correspondence with a great many surgeons who have been kind enough to give me reports of the ages of all cases operated upon. It may be said that they are infrequently seen under 30. After 30 cholelithiasis becomes progressively more common with advancing years. In more than 9,000 autopsies gall-stones were found in one case in every thirty by Naunyn; in persons past 60, one out of every six is affected. The disease is unmistakably more common in women than in men, the proportion being usually given as five to two. In my opinion the disproportion is even greater than this, as is shown by a careful analysis of more than 100 cases operated upon by Louisville surgeons. Of 102 cases where sex was stated 18 only were males. The wearing of corsets, etc., has been held to explain the greater prevalence in females, but it would seem to me that a better explanation is given by their sedentary habits and greater tendency to stomach, liver and bowel troubles.

That the colored race is far less frequently affected than the white seems certain. Prof. Tiffany writes me that while he has done many operations for gall-stones in the white, he has never seen a case in the negro. Prof. Hunter McGuire writes me that he has never seen a case in the negro. Dr. W. E. B. Davis of Birmingham has met with a case in a mulatto, but has seen none in the full-blood. In 106 cases oper-

ated upon by Louisville surgeons but one was in the negro. I have at great pains seen every surgeon in this city and gone over their series carefully with them, and am sure that these statistics are absolutely trustworthy. I have done more, and have gone to Dr. Solomon, Curator of the City Hospital, who has kept a record of every postmortem examination he has made since he has been curator (two years) and in not a single instance have stones been found in the gall-bladder of a negro. It, of course, was examined in every postmortem. He found them frequently in whites.

That the negro should suffer less frequently is, I think, explained by their more active life, better teeth and stronger digestion, coupled with the fact that they do not indulge in the highly seasoned and bilious-making food of the whites; they are also less liable to malaria and other conditions dependent upon, or associated with, a torpid liver.

ANEURYSM.

According to the Eleventh Census Report aneurysm is far more common (3 to 1) in the colored than in the white race. The records of the health office in Louisville agree fully with Billings' statistics, showing that in a population of one to four there were nearly as many deaths in negroes as in whites (14 colored and 18 whites) in the last decennial period.

Of patients treated at the Louisville City Hospital for ten years past, there were slightly more than three times as many negroes as whites, although the proportion of white to colored patients in this institution has been nearly three to one. Sex also has a most marked influence in the etiology of aneurysm. Crisp, in an analysis of 551 cases, found it to be seven times more common in men. Souchon's series of 98 cases shows 76 males and 22 females. An analysis of the cases at the Louisville City Hospital, and those reported to the health office for the past ten years, shows more than three times as many cases in men. The disproportion in the two sexes is, I think, readily explained by the greater tendency of the male sex to arterial degenerations on the one hand, and their occupation and habits on the other. Age has a most direct bearing, as aneurysm rarely occurs before 30. In the series analyzed by me none occurred under 25; there were but three under 30, aged 25, 28 and 28 respectively. The greatest number of cases will be found between 35 and 55. The disease is rare after 60. The following table gives a record of all cases reported to the Health Department of the city of Louisville during the past ten years:

Age	White		Sex not	Colored.		Sex not	Totals.
	M.	F.	stated.	M.	F.	stated.	
1 to 10							
10 to 20							
20 to 30	2				1	1	4
30 to 40	3		2	1	1		7
40 to 50	3		1	3	2	1	10
50 to 60	3				1	1	7
60 to 70		2		4		1	4
70 to 80							
Totals	11	4	3	5	5	4	32

Males. White, 11; colored, 5; total 16. Females. White, 4; colored, 5; total, 9. Sex not stated. White, 3; colored, 4; total, 7.

Aneurysm is apparently far more common in some races than in others, being very frequent and seemingly increasing in England, while it is one of the rarest affections in China, due, it is said, to the non-stimulating rice diet, temperate habits, and phlegmatic temperament of the Chinese. Prof. Hunter McGuire, of Richmond, Va., writes me as follows:

"Aneurysm is much more common in the negro than in the white in my experience." Prof. Tiffany of Baltimore writes of the frequency with which aneurysm occurs in the black race. Nearly all surgeons to whom I have written and from whom I have received replies have remarked upon the greater liability of the black race to aneurysms. I regret to say that few have given any reports of cases, and that these statements are merely impressions gained from a large experience but not substantiated by statistical detail. It is certainly my own conviction that aneurysm is relatively far more common in the negro, and therefore, can not agree with Matas' statement that aneurysms are somewhat less common in the African, a fact he thinks due to their comparative immunity to gout, rheumatism and alcoholism.

TETANUS.

While tetanus is co-extensive with civilization, affecting every race and clime, it is more common in subjects living in hot climates and possessed of dark skins. Negroes, Hindoos, South Sea Islanders, Italians, Spanish and French are less resistant to the germ of Nicolaier. In this country the negro is unquestionably more obnoxious, the infant mortality being heaviest. Appreciating the indifference with which negroes treat minor injuries, and their proverbial uncleanness, we can well understand their greater liability to infection.

The mortality among colored infants is particularly high in comparison to the white, which is explained by racial predisposition on the one hand, perhaps, and by the greater chance for infection through the cord of the newborn, cut as it is with dirty scissors, handled with dirtier hands and wrapped in unclean rags. A large per cent. of colored infants die from trismus neonatorum on Southern plantations, death usually occurring within a fortnight after birth. In the Island of Jamaica and other more Southern countries, the death rate is at times frightful, being from one-quarter to one-half of all infants born; yet the whites here do not suffer to any degree.

According to Billings' recent Census Report, there were 2019 deaths in the census year: 1238 males and 781 females. In 1880 the death rate was greater. Persons from 5 to 15 years show the highest death rate (1.74); those from 15 to 45, 1.04; and over 45, 1.42. The death rate in boys was nearly five times as heavy as in girls. There were sixty deaths in Chicago during the month of July, 1881, due to toy pistol accidents. This, I think, explains the greater prevalence in males; they are simply more exposed to accidents of all kinds and are not more liable, *per se*, to infection.

Tetanus is, or has been in past wars, frequently encountered in military surgery. English soldiers in Spain suffered from tetanus in proportion to one case in eighty wounds; and in the East Indies, in 1872, twice as often. During the civil war our troops were more fortunate. A letter just received from Surgeon Major J. C. Merrill, United States Army, and librarian of the Surgeon-General's Office, is as follows: "I would state that out of 246,712 injuries by weapons of war, 505 (0.20 per cent., or a little over two in a thousand) were followed by tetanus. I may add that over one-half of these cases occurred after injuries to the lower extremities, a fact that has been noted by several authors in other statistics. Your second question, as to the relative frequency of tetanus or erysiphe-

las in colored and white troops, and also in North American Indians, can not, I think, be answered without an amount of search that would require weeks to make it valuable. Isolated cases are reported here and there, but I know of no statistics of sufficient numbers to throw any light on this matter."

The Italians, Spanish and French have suffered more in their wars than soldiers of more Northern countries with fairer skins. Sudden variations in temperature and the depressing effects of defeat, have always increased the number of cases in military surgery.

I am told by Hebrew surgeons that trismus neonatorum is more common than it should be in Jewish infants. It can well be explained, if true, by the manner of performing the ritual circumcision. The Mohel is necessarily surgically unclean and careless in performing the operation, and infection should be easier than if this function were transferred to surgical hands. I am reliably informed by one of my Hebrew medical friends of Louisville that a well-known Mohel of that city is himself infected in a serious way, and a very unfit person to officiate as he does. I am further told by Jews who were born in Russia and other countries, that an affection, which I take it from their description, must have been trismus, is quite common among Jewish infants there. The Jews are a shrewd, wideawake, sensible people, quick to see their own interests, and it is reasonable to assume that time will soon bring about a change of sentiment in this rite.

Health office.—Deaths reported due to tetanus from 1888 to 1898:

White 5, colored 3, total, 8 cases age not given; white 39, colored 16, total 55 cases over one month; white 126, colored 29, total 155 cases under one month. Total, 218 cases. Total white, 170. Total colored, 48.

VARICOSE VEINS.

Varices of the limbs are but seldom encountered in negroes. Of 23 cases of varicose veins of the legs, without ulcer, there was but a single case in a negro, a male aged 44. Of 29 varicose ulcers there was only one case in a negro, a man aged 53. Of the 45 cases there were 13 females and 32 males.

Varicose veins of the limbs are rare before 30, there being but two in the series, aged 27 and 28 respectively. Between 30 and 40 there were 4 cases, between 40 and 50 there were 4 cases, between 50 and 60 there were 6 cases, between 60 and 70 there were 7 cases, between 70 and 80 there were 2 cases. Varicose veins of the limbs are uncommon with Indians, Mexicans and Chinese.

ERYSIPELAS.

The total number of deaths due to erysipelas, in the United States Census Report just issued, was 2663. The death rate per 100,000 inhabitants was as follows: Under 5 years 31.34; 5 to 15 years 0.81; 15 to 45 years 2.80; 45 to 65 years 8.88; 65 and over 38.55. Very few cases occurred in colored persons, so few as to be of no value. A careful examination of the records of our city hospital and the Louisville Health Office shows that the disease is not so rare in the negro as many suppose. Of 79 deaths due to erysipelas, reported in the past ten years to the health department of this city, 17 were colored, which is about the normal proportion, our population being one to four.

Those who are unaccustomed to seeing erysipelas

in the negro are apt to overlook it on account of the color of his skin. Sex would seem to have but little effect. The two extremes of life suffer by far most frequently, young adults and middle-aged persons having it but rarely. Erysipelas of the newborn has not been a frequent affection in Louisville, judging from records of deaths reported to the health department. In ten years there have been 11 cases dying within the first month of life; of these 10 were white.

STONE IN THE BLADDER.

Dr. George Ben Johnston of Richmond, Va., has made a careful investigation of 1068 cases of urinary calculi occurring in twelve Southern States, and finds that the negro is less immune to this affection than has been hitherto believed by many surgeons. It occurs once in every 11,732 whites, and in the black race once in 55,305. It is, then, nearly five times (4.72) more frequent in the Caucasian. Sex was specified in 708 cases, there being 691 in males and 97 in females; more than seven times as frequent in the male sex. The ages of his cases in this large and interesting series were not given, I regret to say. Gross analyzed 6042 cases of urinary calculi with reference to age, and found that:

2334 occurred from 1st to 10th year.
1079 occurred from 10th to 20th year.
513 occurred from 20th to 30th year.
353 occurred from 30th to 40th year.
422 occurred from 40th to 50th year.
536 occurred from 50th to 60th year.
587 occurred from 60th to 70th year.
201 occurred from 70th to 80th year.
17 occurred from 80th to 90th year.

It will be seen that more than one-half of all cases occurred within the first two decades of life, and that the first furnishes more than double as many cases as the second, the latter more than double the number in the third decade. The ratio is then pretty well maintained until the sixth decade, when an increase is noted; this increase to be still further augmented in the seventh decade. When it is remembered that there are relatively fewer persons living in the sixth and seventh decades, it will at once be seen that the two extremes of life, the first and seventh decades respectively, are most obnoxious to urinary calculi. Stone in the bladder occurs everywhere, affecting every race, but it is found in some countries more frequently than in others. In North America it is found most frequently in Kentucky, Tennessee, Ohio, Missouri, North and South Carolina, Virginia and Georgia. New England is relatively exempt, as are also Mississippi, Alabama, Arkansas, Louisiana and a few other Southern States. Stone is common in France, Austria, Hungary and Russia; seldom seen in Spain and Switzerland. It is also frequent in England, though less so in Ireland. It is very common in India. In China gravel and calculus are, according to Gudgeon of Pekin, among the rarest of affections. Stones are common enough at Canton, but of infrequent occurrence at other points. It has been supposed to be due to the fact that the inhabitants here live largely upon fish, but this can hardly be, as Gudgeon states that the diet, water and habits are the same here as at other Chinese centers.

Opium eating is supposed to lessen the liability of the Chinese, as a race, to stone. Certainly it is not the drinking of limestone water, as river water is universally drunk and very generally boiled before drinking. Little cold water is drunk in China. A number of my surgical friends in the Medical Corps of the

United States Army assure me that stones in the bladder and kidney are rare among the North American Indians, and the reported cases will generally be found to have occurred as a result of traumatism, a nucleus in the bladder inviting the deposition of the solid constituents of the urine around it. I have reports which justify me in thinking that vesical calculi are more common with Mexicans, one operator in the small town of Santa Fé reporting five operative cases.

STONE IN THE KIDNEY.

Practically all that has been said of vesical calculus pertains with equal force to the renal variety. The two extremes of life are most obnoxious; males also suffer about twice as often as females, some placing it as much as three times as frequently. Some excellent authorities, however, as Duplay, Reclus and others, think the two sexes equally affected. It is very certain that the disproportion which exists between the two sexes in vesical calculus does not exist here, and does occur in the former disease for obvious anatomic reasons. The short, capacious urethra of the female easily allows gravel to pass, which in the male must remain in the bladder and act as nuclei for future stones. No cases have been reported to me as occurring in the negro.

OVARIAN GROWTHS.

Ovarian tumors, cystic and solid, occur at all ages and in every race so far as I know. The more usual form of growth is cystic in character, simple or dermoid. Both varieties may be congenital, frequently are, and only await the stimulation which puberty brings to awaken them into renewed life. Therefore, while the records abound with instances of operations done upon simple and dermoid cysts in children by operators all over the world, we may say that prior to puberty ovarian growths are relatively rare. An infant four months old was successfully operated upon by D'Arcy Powers at the Victoria Hospital for an ovarian cyst containing fifty-nine ounces of fluid, reported only a few weeks ago. Hoffman reports an unsuccessful case at three months, the tumor containing six to eight pints of fluid and the solid portion weighing $2\frac{1}{2}$ pounds, in all 10 pounds. Busch operated unsuccessfully upon an ovarian cyst in a child 24 months old. de Santa Anna removed a dermoid cyst in a child 1 year old, and Roehmer one from a child 20 months old, and Schwartz one from a child 4 years old. Mears, Barker and Rein have operated in cases of children under 7 years of age; while Thornton, Lucas, Hamaker, Cupples and Chenoweth have operated in children from 7 to $7\frac{1}{2}$ years. Sir Spencer Wells and many others report operations in children under 10 years of age.

As to the other extreme of life, the same may be said, the octogenarian being not immune. A great number of cases have been reported in women past 70, and a reasonable number 80 and beyond. Cartledge of Louisville, recently operated successfully upon a case past 81. Hoffman reports a case at 82. But, while it is true that ovarian cysts may and do present themselves at any age, it is also true that they are most likely to develop during the sexual life of the host. Puberty stimulates not a few to rapid growth, especially dermoids: therefore, it is not unusual to find such growths under 20. They, and all other ovarian tumors, are more common, however, during the next three decades of life.

Much has been written about the immunity of the negro to cystic diseases of the ovary, yet literature teems with instances of the affection in the colored race. It is unquestionably less common in the negro, but the difference in liability of the two races which is supposed to exist by many surgeons is not supported by careful statistical data. A great many ovarian cysts in the negro, full-blooded as well as mulattoes, have been reported to me by various surgeons of the South. The records of the Health Office of the city of Louisville show that there have been nearly one-third as many deaths from ovarian tumors in the colored race as in the white during the past ten years. This would indicate them to be even more common than in the white, as the normal proportion of colored to white population is one to four; yet this is not the case, I fancy, as the discrepancy is easily explained, I think, in several ways. In the first place the colored race is less resistant to surgery of all kinds, which fact seems clearly established by Matas, from the enormous experience of the Charity Hospital of New Orleans. In the second place negroes are oftentimes operated upon by less skilled abdominal surgeons and under environments less advantageous than whites enjoy.

I am, to conclude, satisfied that the supposed immunity which the negro is thought by many to enjoy does not exist, except to a limited degree, if at all; for if they were immune at one time, the immunity hitherto enjoyed, has, like unto that from malaria and yellow fever, almost wholly disappeared. The size of ovarian growths varies from a walnut to a mass aggregating a weight of 245 pounds, the largest tumor on record, removed by Cartledge of Louisville, within the year. A female laparotomist of Japan removed one weighing considerably less. Keen of Philadelphia, removed a very large tumor in a girl 15 years of age, weighing 111 pounds, the child weighing, after removal, 68 pounds.

Malignant disease (usually sarcoma) of the ovary may occur. It is four times as common before the age of 15 as afterward; 25 per cent. die from any operative interference, and nearly all within a year from recurrence. Convalescence is also tedious in those who survive operation.

CONGENITAL DEFORMITIES.

Harelip, cleft palate, clubfoot, spina bifida and all congenital deformities are certainly less frequent in the negro, judging from the experience of Louisville surgeons and other practitioners in Southern cities to whom I have written. But a single case of harelip and cleft palate, both in the same individual, has been operated upon in Louisville, so far as I can learn from personal interviews with its surgeons and examination of the records of the city hospital and college clinics, for the past ten years. Clubfoot and spina bifida in the negro have never been encountered in my practice, nor so far as I can learn in the practice of other Louisville surgeons. Dr. Vance is positive that he never saw a case.

Congenital deformities of all kinds are also reported to be most rare with Indians. The only deformity reported by any of the many army surgeons to whom I have written was one case of clubfoot and a double harelip, both in Sioux children. The clubfoot was in a boy and the sex of the harelip case was not given by the reporter, Dr. William L. Kneeder, captain and assistant-surgeon, United States Army. Other army

surgeons who have answered my inquiries have all stated that they have never met with these deformities in Indians; most of them, however, stating that they may not be so rare as their observations would indicate, for it is the custom of the Indians to put deformed children to death soon after birth. The Jews, I am informed, suffer less than others from congenital deformities. The Mexicans as a race suffer more frequently than Indians from all congenital deformities, and a number of cases of harelip, club-foot, supernumerary digits, etc., have been reported to me. One family in the practice of Dr. J. M. Diaz of Santa Fé, N. M., is remarkable for each of six children having six fingers and as many toes upon each hand and foot.

APPENDICITIS.

That appendicitis is relatively a rare disease with negroes is a fact substantiated by all Louisville surgeons and others from whom I have received answers to my questions. In an analysis of 250 cases operated upon by Louisville surgeons, but 5 cases have been reported in negroes. This would indicate a striking immunity, as it shows the disease to be only one-tenth as common in the black race.

Sex.—Nearly all writers on this subject have remarked upon and tried to explain the greater frequency of appendicitis in the female. That it is more common in men none will deny. Just what the difference in liability is, it is not easy to say. Fowler's statistics indicate it to be rather more than four times as common—142 men, 35 women. In 92 cases analyzed by myself there were 58 males and 34 females.

Age.—The influence of age is not less marked than that of sex and race. The disease is common between 15 and 35. Though Hold, Villard and others report cases under 5 years of age, but few are of record, and we are justified in saying that the first quinquennium of life enjoys a practical exemption from this affection. It is rare in the second quinquennium, more common in the third, liability further increased in the fourth, and reaching the maximum in the fifth quinquennial period, then declining slowly in the sixth, seventh and eighth to become thereafter a rare disease. The average age in 92 cases was 23.13 years.

I have analyzed 92 cases with reference to age and sex: Of these there were 58 males and 34 females. The ages were as follows:

	Cases.
Under 5 years (3 $\frac{1}{4}$ years)	1
5 to 10 "	9
10 to 15 "	11
15 to 20 "	18
20 to 25 "	19
25 to 30 "	16
30 to 35 "	4
35 to 40 "	4
40 to 45 "	5
45 to 50 "	2
50 to 55 " (51, 52 and 53)	3
Total	92
Average age	23.12 years.

In Fowler's 169 cases (*Annals of Surgery*, May, 1894) 142 were males and 35 females. The age of the youngest was 2.5 years, the oldest 68 years. In the youngest case the disease was tubercular in character. This was the only case occurring under 5 years of age.

	Cases.
Between 5 and 10 years	8
" 10 " 15 "	21
" 15 " 20 "	29

Between 20 and 25 years	43
" 25 " 30 "	23
" 30 " 40 "	28
Over 40 years	16

Experience of Louisville surgeons:

James M. Holloway—"I recall but one case in the negro." Ap Morgan Vance—"Forty-four cases, one negro; average age 24." A. Morgan Cartledge—"I have operated but once on the negro in more than one hundred cases; first, second, third decade." J. Garland Sherrill—"Three cases; none in negro: aged 55, 20 and 38." H. Horace Grant—"About 5 per cent. in negro." W. O. Roberts—"About twenty cases; one in negro." T. B. Greenley, Meadow Lawn, Ky.—"Have never seen case in negro." J. R. Buist, Nashville, Tenn.—"Common from 5 to 40; rare in negroes." Hunter Maguire, Richmond, Va.—"I see very little difference in appendicitis in the two races; probably it is a little more common in my experience in the white." L. McLane Tiffany, Baltimore, Md.—"I have operated upon two negroes for appendicitis; one a male child, one a young male adult." In more than fifty operative cases I have seen appendicitis but once in the negro.

RECTAL DISEASES.

That all periods of life do not suffer from the several diseases of the rectum is apparent to every observant practitioner. Children frequently have prolapsus ani and polypi, but rarely other rectal affections. Elderly persons also enjoy a relative immunity to rectal disorders, as they suffer infrequently from the more common troubles, hemorrhoids and fistula. Cancer, to be sure, is more frequent with them, but it is, comparatively speaking, a rare disease. Middle life is the time when piles, ischiorectal abscesses, fistulae and fissures are most prone to occur. They are all frequent. An analysis of 70 cases of hemorrhoids shows only three patients under 20 to have suffered—at the ages of 14, 18 and 19 years respectively.

Suffered in the third decennium	14
Suffered in the fourth decennium	15
Suffered in the fifth decennium	19
Suffered in the sixth decennium	19
Suffered in the seventh decennium	3
Total	70

Sex seems to have an influence, as less than one-third were females (females 23, males 47).

Race has a more marked influence, there having been 60 whites to ten colored. As these were hospital cases where the proportion of colored to white patients was 1 to 3, piles seem to be more than twice as common in the white.

Hemorrhoids are said by army surgeons and others to be rare among the North American Indians. The celebrated authority, Van Buren, who spent some years among them, stated that he never saw a case of piles in an Indian. Dr. F. A. Winter, assistant-surgeon, United States Army, informs me that hemorrhoids are reported to be common with the Mexicans, and their liability is supposed to be due to the free use of mescal. Piles are common with the Mexicans of New Mexico where pulque is not used as a beverage, and is supposed, by nearly all of the practitioners of the Territory, to be due to the free eating of Cayenne pepper.

I am told by careful observers doing much practice among the Jews that they are, as a race, liable to rectal affections. Dr. Gerster of New York, for many years surgeon to Mt. Sinai Hospital, where the

patients are mostly Hebrews, gave it as his opinion in a paper read before the American Surgical Association, that this race frequently suffered from rectal affections. He expressed the same opinion to me personally.

Fistula in ano is just as common, or nearly so, in the colored race as in the white. An analysis of 43 hospital cases shows 33 in whites, 10 in negroes; normal proportion of colored to white, nearly 1 to 3. The liability of the negro to tuberculosis explains his being more frequently affected with fistula than piles. Twenty-seven of the series were males and 16 females.

Age.—The first decade, as in piles, furnishes no cases; the second but 5 cases, aged 13, 16, 17, 18 and 19 respectively.

	Cases.
The third decennium furnishes	12
The fourth decennium furnishes	10
The fifth decennium furnishes	4
The sixth decennium furnishes	11
The seventh decennium furnishes	2

Fistula is undoubtedly more fatal in the colored race. Of the fatal cases reported to the Louisville Health Office during the past ten years, there were nearly twice as many deaths in negroes, although the normal proportion of colored to white population is only 1 to 4. This would indicate fistula in the negro to be nearly eight times as fatal as in the white. The excessive mortality in the colored race can be explained by their greater tendency to tuberculosis, sepsis and syphilis.

ACUTE INTESTINAL OBSTRUCTION.

Omitting congenital malformations as a cause of obstruction, we have first, invagination or intussusception; second, impaction of foreign bodies, notably gall-stones; third, volvulus or twisting of the bowel upon its axis, said to be due to elongation of the mesenteric attachment of the gut; and fourth, internal strangulation either due to an inflammatory band, a Meckel's diverticulum, or a protrusion of the gut through some internal opening. I have only chosen to consider acute obstruction, as it would seem to have a more direct bearing upon the questions of age, sex and race.

Intussusception.—Intussusception causes at least one-third of all cases of acute intestinal obstruction. According to W. Brinton, who analyzed 12,000 post-mortem examinations, intussusception causes about 43 per cent. of all cases. Leichtenstern and Fitz place the figures at 38 per cent., others place them as low as 30. Intussusception is *pre-eminently* an affection of *infancy* and *early childhood*. L. Emmett Holt has collected 385 cases of intussusception in young children; 141 were under six months old, 89 between six and twelve months, 32 between the first and second year, 96 between two and ten years. It will be seen that considerably more than one-half of these cases occurred within the first year. It was encountered more frequently in males than in females—174 against 94. In adults intussusception is said to be more common in women than in men (Park's "System of Surgery"). At least one-half of all cases of intussusception take place at the ileo-cecal junction. Of the remaining cases twice as many will occur in the small intestine as in the colon.

Impaction of foreign bodies.—Foreign bodies, hardened feces, and especially gall-stones, may occasionally cause intestinal obstruction. From statistics, which I have carefully examined, it would seem that

this will explain about one case in fifteen of intestinal obstruction. I have seen two cases caused by impaction of enormous gall-stones, both in elderly subjects (white) and in females. Occasionally an instance will be met with in a child who has swallowed foreign bodies. Cases due to fecal impaction are usually in elderly subjects, a decided preponderance being females.

Volvulus.—Intestinal obstruction due to volvulus is comparatively rare. It nearly always occurs after middle life, frequently in elderly people, and is three to four times as common in men as in women. Elongation of the mesentery, which is supposed to act as a cause, may be congenital, but is usually exaggerated late in life as a result of prolonged traction, therefore explaining the relative frequency of this affection in elderly subjects, just as hernia is accounted for in the same way.

Internal strangulation.—This variety of intestinal obstruction is the most frequent of all. It may be caused by a Meckel's diverticulum, inflammatory bands, retroperitoneal herniae, prolapse of the intestine into an abnormal pouch, or be a form of hernia. An intussusception is closely identified with the first decennial period of life, and volvulus with elderly subjects, this variety is associated with those between the two extremes of life. This is, as we might expect, on account of occupation, exposure and the diseases to which we are liable during the active period of existence. In men it may follow appendicitis caused by a band constricting the bowel; in women it not infrequently follows pelvic inflammation.

Race.—Of 45 fatal cases of intestinal obstruction reported to the health office for the past ten years, 40 were white and 5 colored; 26 males, 19 females. This would indicate a mortality in the white race exactly double what it is in the black. (Normal population one to four).

White, male 23, female 17; color not stated 10; colored, male 3, female 2; sex not stated 1; total 56.

CHAIRMAN'S ADDRESS.

[ABSTRACT.]

Presented to the Section on Obstetrics and Diseases of Women at the Forty-ninth Annual Meeting of the American Medical Association, held at Denver, Colo., June 7-10, 1898.

BY JOSEPH PRICE, M.D.

PHILADELPHIA, PA.

In the early history of gynecology the real pioneers had not only the scientific knowledge to attain, but principles to practically apply, means and methods to adopt without the aid of precedents or the counsel of fellow practitioners. It has always been difficult to perfect and establish a procedure.

McDowell operated with a mob at his door. Nineteen and ten years before McDowell's operation, William Bainham did two successful operations for ectopic pregnancy. Doubtless the success of Bainham's operation greatly influenced McDowell and was inspiration in his own heroic and successful work. Yet notwithstanding this success there was a suspension of the operation for a quarter of a century. Not again was the operation resorted to until 1843. Then by John Light Atlee of Lancaster, Pa., and John Clay of Manchester, England. To the extent to which these pioneers carried their work, we have in our own work, without material change, followed their methods,

perfecting somewhat the lessons they taught and enlarging the field of their application. Ignorance and prejudice yet face us at every turn, repeatedly opposing from sources from which we have the least right or reason to expect it. The old conflict is not yet altogether dead, buried and out of sight and hearing. Those whose courage was great, motives worthy, were abused for throwing light into the darkness in which the great body of the profession groped.

To illustrate and somewhat contrast the spirit of then and now we let Dr. Atlee speak: "It is well known that from the earliest period of ovariectomy in Philadelphia down to the present time it has been my invariable custom to invite members of the profession to witness the operation, in order that they might be able to form a proper opinion of its character and to judge of its propriety. There was not a prominent medical gentleman in this city that had not such an opportunity. It was a rare circumstance during the probationary stage of the operation for any one to accept the invitation cordially and gratefully. Some did so coldly, as if conferring a favor upon me, others politely declined, others positively refused and emphatically condemned the operation, while others took the invitation as an insult." "Gentlemen who were bold enough to witness the operation were even directly accused by their professional acquaintances of being *particeps criminis* in committing murder, notwithstanding these murdered patients recovered. Some high in the profession, against all ethical consideration, would call upon the patients who had finally decided upon the operation for the purpose of warning them against me and certain death. The colleges proclaimed fiercely against the operation as unjustifiable and criminal." Professor Meigs thus emphatically expressed himself: "I detest all abdominal surgery, I am free to say that I look upon all operations for the extirpation of the diseased ovary as not to be justified by the most fortunate issue in any ratio whatever of the cases, or in other words, not to be justified by any amount of success."

It is very good for men to be honest in their opinions, it is very much better for them, in spirit and in fact, to be right in them. Oliver Wendell Holmes has aptly said: "There can be no reason why the student of science should limit his attention to his specialty, though there is abundant reason why he should avoid any attempt to make researches over too wide a range of ground. His researches in his own special corner of science will lose nothing in value, but gain greatly, by an occasional survey of the work of others, only let him not pretend to take part in actual work in many parts of the field he surveys." All troubles to which women are subject, medical and surgical, are found within the field of the general practitioner. He should be a skillful diagnostician and should be competent to deal directly with many minor gynecologic troubles.

In the last decade the younger school of gynecologists have unfortunately lost interest or neglected plastic surgery. The great majority of them have been seized by the strange, inexplicable infatuation for the surgery of the peritoneal cavity.

The vital questions relating to plastic work have largely dropped out of the discussions of our societies, there are few recent contributions to our literature worthy careful study. Along this line we are slow in following the footsteps of the older specialists, the

compeers and followers of Sims. Sims, followed by his pupils, gave his plastic operations, methods and instruments, as yet not improved upon by modification or otherwise. All know the beautiful results following careful and successful work, and fully recognize that it is not work to be done by a mere apprentice to secure desired results. The reports of vesico-vaginal fistulae run about as follows: "Two attempts at closure resulted in benefit to the patient, reducing the size of the fistula." Distressing conditions are not corrected, because gynecologists are not giving the subject the careful study its importance demands. My own experience can not differ widely from that of many others. In a recent series of cases I had four of vesico-vaginal fistula. They were sent to me either by their friends or physician. In each case there had been three or four attempts at closure, all failures. These failures were explainable from the certain premises that the patients had not been thoroughly prepared for operation by the common methods so fully detailed by Sims and his pupils. Operations for opening into the bladder, for complete laceration of the sphincter are failures in great numbers. Some operators seem to miss the sphincter absolutely. Careful training in plastic work is of more importance than in abdominal surgery. An apprenticeship in a gynecologic dispensary gives a practical knowledge of skin diseases about the external genitals, of parasites and growths, and also lacerations, that is rarely obtainable in private practice. Simple ovariectomies are easy, compared with the delicate, tedious and difficult work of dealing with mutilations where they are extensive, where we have lacerations of the urethra, perineum, bladder and cervix, or a very common distressing disorder, uterine displacement, which received prolonged and careful attention at the hands of the early and prominent gynecologists. Of late years the preparation of the patient and soft parts for operative interference has not been sufficient. Uterine displacements were treated successfully by simple methods by the early gynecologic specialists. Hodge, Sims, Gaylard, Thomas, Albert Smith and many others of equal prominence at home and abroad, corrected the displacement or put the uterus in the normal or desired position with some form of properly adjusted pessary. Displacements are quite generally shirked or neglected. The very common office attempt at local treatment and the correction of displacement is an error and about always a failure. Both office and the run-about treatment in the whole range of gynecologic disturbances are to be condemned. Women with uterine posterior displacements should be put to bed, uterus put forward, all lacerations repaired and a well-fitting pessary placed. Many general practitioners who make no pretense of special skill or knowledge, succeed beautifully in correcting displacements; this they do by putting the patient to bed and correcting the retroversion or the retroflexion by using one of the varieties of the Albert Smith or Hodge pessaries, with Gayland Thomas modification. The great, round, soft rubber rings are useless and harmful, but are in much too common use. The stem girdle pessaries are of but little value. All lacerations should be carefully repaired and posterior displacements carefully corrected before any of the usually adjusted pessaries are placed.

The rest treatment for the correction of displacements is the shortest, surest and most satisfactory. Anterior dressing of the uterus for a few days, with the

patient remaining at rest, in the Sims position, favors a very speedy recovery.

It should not be taken that there are no risks associated with these mechanical appliances. Early in the history of the use of the pessary there were numerous accidents. I have removed them when very careful dissection was required, when the patient had worn them for ten or twelve years and had lost all knowledge of their presence. I have found them deeply buried and the patient dying. No great skill but great care is to be exercised in their application. Men familiar with placing them get good results, and rarely have accidents. The statistic records of accidents have a warning in them. An eminent physician has published an analytic monograph in this relation and tabulates results as follows: "Twenty-three cases of perforation of the rectum by the pessary; 20 cases of perforation of the bladder alone; 10 cases of perforation of the bladder and rectum; 1 case of ureteric fistula alone; 1 case of ureteric and vesico-vaginal fistula; 1 case of perforation of Douglas' pouch (neither fatal); 3 cases of perforation of the vaginal wall, the extruding portion of the pessary lying in the pelvic connective tissue, and 6 cases of the entry of a vaginal pessary into the uterus."

This record sounds a warning as to the importance of care in the application of the pessary. There has been no very recent startling of the profession by the announcement that someone had invented a new pessary. It is to be anticipated that during the meeting of our ASSOCIATION there will be a very lively shucking out of new methods of procedure.

All we know of the physiology of uterine action compels us to regard the uterus and ovaries as the strongest links in the chain of woman's health of mind and body.

Be not deterred by false sentiment or the jealousies of those who would rather keep their patients in their own hands than see them cured by others from doing what we know to be our duty.

"Do we not all know by sad experience of the years of useless suffering that might have been spared, of lives that might have been saved, of the ruin of conjugal happiness that might have been averted, of material usefulness that might have been preserved had an accurate diagnosis been arrived at in the earlier stages of uterine disease and a proper line of treatment adopted.

"In prolonged disorders of the uterus, resulting in enlargement, hyperplastic deposits or a process of fibroses following on arrested involution, in those secondary pathologic conditions attending upon lacerations of the cervix, in deep erosions, in unrelieved versions and flexions, in tubal enlargements and displacements, and in chronic affections of the ovary, as sequelae of pregnancy, we find not only these reflex conditions present, but more aggravated pathologic consequences and more serious disturbance of function." These are the mature opinions of MacNaughton Jones and other eminent English specialists and general practitioners. I strongly direct attention to this subject because it has not received the attention its importance deserves. It has had a few able and courageous champions who have had to contend against obstructions raised chiefly by members of the profession from motives which we will not attempt to analyze.

I am satisfied that many cases of nervous disorder could be averted or cured by early and careful atten-

tion to uterine and ovarian troubles and the examination of pelvic viscera. We can only clear away doubts and establish safe scientific methods by utilizing the lessons of the observations and clinical experience of men who are working among facts.

Our surgery is very much more than an art, it is also a science without limit, a science with no tolerance for obstructionists, no false deference for the venerable, that replaces the old with the better new. We are not accepting mere opinions for truths, we are demanding scientific and practical tests, that old knowledge shall pass the crucial test of modern experiment and analyses. We recognize that we have not reached the "last results," that there is enough we do not know to keep us from falling into a condition of inertia, to furnish us with extensive "happy hunting grounds." I could not refer to many of the evidences of our progress without raising controverted questions.

We have given and continue to give names to things we do not understand, we know little or nothing about. We have cancer, typhoid and puerperal fever, they are names for conditions; there we are estopped; finding ourselves face to face with the unexplained, we grope for the cause and remedy. Among the best evidences of our progress are our medical journals. They are largely to be credited with the scientific spirit, the earnestness of research diffused through the profession, they bring forward questions of direct and current interest, touch our every-day work, give those facts of our clinical experiences which constitute our best lessons, they index our progress. Our periodical literature has largely taken the place of our old text books. Our leading minds, where they have something to say, say it through our magazines, and give us the best they know. To the busy physician the JOURNAL is largely his literary world. The JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION speaks for us as an ASSOCIATION, it is our official organ, it represents our scientific spirit and activities, the results of our study and research. Through it the teachers in our colleges, the specialists and general practitioners speak. However able and enterprising may be the editor, the JOURNAL will not rise above the high-water mark of the scientific intelligence of the AMERICAN MEDICAL ASSOCIATION—the great representative body of the American medical profession—by its report of our work we will be judged at home and abroad.

In conclusion I can only make brief reference to obstetrics. It is gratifying to know that the mortality in child-bed has been greatly reduced; this is largely due, both in lying-in institutions and in private practice, to cleanliness of environment. In maternity cases it is in the great majority of instances dirt and meddlesome or unskillful instrumental interference that kills. To have skillful obstetricians, the teaching of our schools should be more thorough, theoretically and practically. Our students pay liberally for their advantages and should be dealt with liberally; every avenue to thoroughness should be open to them. The professor who teaches him obstetrics should know the science and art of his subject and how to teach it. As a rule the professor of obstetrics is not an enthusiast in his line, nor does he infuse interest and enthusiasm in the student; his teaching is largely perfunctory. He teaches one subject, or professes to, while he practices another. About all of them *want to be* gynecologists and

specialists. Some of them take to neurology, which requires great versatility of genius, the art to write poor poetry and indifferent fiction. There are ample facilities in our educational centers for practical education in obstetrics; hospitals, courts and alleys are open. The student should be given that which will enable him, when he goes home, to go to work and do good work.

ORIGINAL ARTICLES.

THE QUALIFICATIONS AND DUTIES OF THE MILITARY SURGEON.

BY LIEUT.-COL. N. SENN, U. S. V.

CHIEF OF OPERATING STAFF WITH THE ARMY IN THE FIELD.

Nearly five months of continuous service with the army in the camp and field has afforded me an excellent opportunity to make a practical study of the above subject. This time was spent in Camp Tanner, Springfield, Ill.; Camp George H. Thomas, Chickamauga, Ga., and the Cuban campaign, the time being about equally divided in the different places. The first four weeks were occupied in Camp Tanner, where I assisted in the capacity of Surgeon-General of the State in the organization of the State troops. This service brought me into closer contact with the National Guard of our State than at any time before. A physical and professional examination in which I took part brought out the shady as well as the sunny side of their qualifications. The result of my experience here convinced me that the average National Guard surgeon is a faithful doctor, with more than average professional ability, but, with few exceptions, lacking the necessary military training in performing satisfactorily his administrative duties. This is a part of his education that has been sadly neglected in the past and should receive more attention in the future. Very few States make provision for physical examination of the medical officers, consequently some of them have entered the service totally disqualified for participating in an active campaign. Two of the candidates for the volunteer service from the National Guard of Illinois were rejected on this ground. The four weeks' service at Camp George H. Thomas as chief surgeon of the Sixth Army Corps opened up a wide field for extended observations in making comparisons between the work done by the surgeons of the regular army and of the National Guard. The surgeons of the United States Army are all men of superior education, splendid physical development, and those who have been in the service for several years are well versed in the routine work of the Medical Department. However, in all matters pertaining to medicine and surgery the average National Guard surgeon more than holds his own. This superiority of the National Guard surgeon over his colleague of the regular army is no reflection on the latter; it is the natural outcome of circumstances, which made such a difference inevitable. The young army surgeon has to spend many years at small and often out-of-the-way posts, where the opportunities for clinical experience and intercourse with professional colleagues are necessarily limited. He naturally soon falls into the monotonous and routine work of the post life, with little or no inducements to continue his post-graduate, scientific and medical studies. When the time comes to pass an examination he wakes up from his lethargy suffi-

ciently to go through the different compends to prepare himself for the coming ordeal. He breathes easy after he has reached the major's rank, as this promotion forever closes the door of the much-dreaded green room. From now on he is in the line of slow promotion without any extra exertions on his part. He receives his salary and looks confidently for assignments to posts where he can spend the balance of his life in ease and luxury. He has reached a time in life when he feels that he can avail himself of the work of his subordinates without interfering with his emoluments or his position in social and military life. He is conscious of the fact that he has reached a rank and a station in life where it is proper for him to look to his assistants to do the drudgery which he had become accustomed to in the past, and begin to enjoy the life before him. It is different with the military surgeon taken from civil life. He emerges from the turmoils of family practice. From the day of his graduation he has tasted the bitter fruit of active competition. His work has been watched with an envious eye and subjected to sharp criticism by his neighboring colleagues, old and young. He felt from the very beginning of his professional career that success depended upon his own exertions. The average American practitioner is a hustler. He is willing to work night and day to gain a lucrative practice and the social position which goes with it. With few exceptions he knows that what he has learned in college is but the entering wedge to a comprehensive knowledge of the practice of medicine and surgery. He knows that our profession has become a progressive one. His college education tells him what is new today will be old tomorrow. He looks with pity on his colleagues, advanced in years, whose language and practice convince him that they have fallen into a dangerous rut. He reads the numerous medical journals, the great avenues of recent medical literature. He spends his scanty income in purchasing new books and instruments for scientific investigations. All requisitions are made on himself and are honored only by writing his own checks. He joins medical societies, large and small, and attends their meetings regularly. He listens intently to the reading of papers and discussions to increase his store of knowledge and returns to his limited field of action better prepared to battle against disease. He mingles freely with the members of his profession, always ready to absorb and digest new ideas. He makes frequent pilgrimages to his alma mater or some post-graduate school to familiarize himself with the most recent advances in medicine and surgery. Social life has no attractions for him; he has entered the profession for the sole purpose of becoming an influential and successful practitioner. This is the kind of material our National Guard surgeon is made of. No wonder he outweighs the professional military surgeon in practical knowledge required in the treatment of injuries and disease.

The exacting and often onerous duties of the military surgeon in times of war require special qualifications to prepare and fit him for his work. He is not only expected to be well versed in theoretical and practical knowledge of everything pertaining to the practice of medicine and surgery, but he must be endowed with qualities both of mind and body upon which he can rely when engaged under the most trying circumstances. In field work he has often to perform the most difficult tasks with very limited

resources. In such instances good common sense and deliberate action go much further in accomplishing what is desired than the finest scholarship and the most profound logical reasoning. The man who can in a few moments extemporize a well-fitting splint out of the simplest materials and perform with the contents of an ordinary pocket case the most difficult operation will do vastly better work on the battlefield than most professors of surgery and the most brilliant operators in civil practice. The surgeon who understands the principles and practice of good cooking is of more service to the troops than the one who can repeat, word for word, the contents of the most exhaustive treatise on materia medica and therapeutics. The medical officer with a full knowledge of hygiene and sanitation and endowed with the faculty of making a rational, practical use of it is preferable to the most expert clinician, as in military practice it is more important to prevent than to treat disease, no matter how successfully and scientifically the latter may be conducted. The all-around medical officer must be a good mechanic; he should know how to use the carpenter's and blacksmith's tools, how to row and sail a boat, how to make a raft and occasionally he will have reason to be thankful if he has learned how to pack a mule and drive an ambulance team. His

every particle of his reserve strength to perform a critical operation with a view of saving the life of another. Achievements of this kind are possible in private practice but are entirely out of the question in military service. The physical condition of the military surgeon must be as nearly perfect as possible. A physical examination as thorough and as painstaking as in the case of a private can only decide upon the necessary physical qualifications of candidates for commission in the medical service. For good reasons this rule is followed in the selection of medical officers for the regular army and there is no ground why the same requirement should not be exacted in the National Guard. During my service at Chickamauga and in the Cuban campaign, I saw more than one volunteer surgeon who ought to have been excluded from the service for physical disability. During a campaign the loss of a single medical officer may prove a great disaster. Of all commissioned officers the surgeon is the most indispensable. The vacant place of a line officer can be filled at a moment's notice without any serious loss to the service; not so with the surgeon. His position is one requiring special training and one that can not be filled without crippling the medical service at some other point. For this, if for no other reason, the medical officer must

Transfer of wounded to the hospital ship *Relief* at Arroya.

miscellaneous knowledge of matters and things entirely outside of his legitimate province will be constantly drawn upon from different sources and the more he knows and is willing to impart the more he will be useful and popular. The man who enters the medical department of the army under an impression that he is only expected to treat wounds, set broken bones and prescribe for the ordinary camp ailments makes a serious mistake and will be surely a disappointment both to himself and to those he is expected to serve.

Physical condition.—The ideal military surgeon in possession of the necessary mental and physical qualities to make him so is seldom seen. The most active brains are often found in a frail body. I have often seen in civil life surgeons of great reputation struggling with disease or its effects, or the victims of some congenital or acquired defects, who were wonders in the operating amphitheatre in spite of such disability. I have seen more than once the saddest of all spectacles in professional life—a surgeon, himself the subject of an incurable disease, muster into service

The Spanish military hospital in Ponce, Porto Rico.

be in sound health and able to cope successfully with the hardships of a campaign. In battle, and during the prevalence of an endemic or epidemic disease, the medical officer is the one above all others whose strength and endurance are taxed to their utmost extent. His services are required by day and by night. He has no rest, and unless in possession of an iron constitution, his strength fails him and he becomes, if not a fit subject for the hospital, at least a physical wreck, who, if he persists in continuing his work, will often do more harm than good. A number of such instances came to my personal notice during the Cuban campaign. A medical officer should not only be in full possession of health and all that this implies, but he should have been in training to endure hardships of all kinds from early childhood. He need not necessarily be an athlete, but he should be able to walk twenty miles a day or ride forty without fatigue and then be ready to do a night's work should an emergency demand it. The dancing halls and club houses are poor training schools for a successful military career. The labor and hardships

encountered in hunting are best calculated to prepare the body for a life of great activity and privation. Frugal living will not only prove conducive to the maintenance of health but will be the best means of initiating the surgeon to the uncertainties of the commissary department when on the march or in the field.

Let every one who chooses the military career dispense with unnecessary clothing and luxuries during early life in order to accustom and adapt himself for his life work, which in time of war will bring the inevitable amount of vicissitudes and even suffering. The medical officer must be a good horseman, which here not only implies a good rider, but a knowledge of the usual ailments of horses, the treatment, feeding and care of the animals. To sum up, the military surgeon must be a man of vigor, made so by birth and training, with as few requirements in his habits of living as possible, in order that he may resist to the highest degree the influences of climate and disease and prepare himself for the hardships and privations incident to active warfare.

Mental qualifications.—A proper and adequate preliminary education is exacted of every surgeon in

resent. The elevation of the standard of medical education by most of the medical schools throughout the country will gradually wipe out this blemish, but it will take many years before all of the diplomas can be accepted as sufficient proof that their possessors are entitled to recognition by the medical department of the different States. Let us hope that a speedy and radical reform may be instituted in the different States which will accomplish the desired object, and which will make the commission of a medical officer of greater import in showing a higher degree of preliminary and professional proficiency than the diploma of any of our medical colleges. This is a desideratum for the realization of which every one interested in the success and usefulness of the national guard should willingly use his influence. Fortunately, there are no specialties in military practice. The medical education of a military surgeon must be of the most liberal and broadest kind. His practice is so varied that he may have to be physician, surgeon, oculist, aurist, etc., the same day. The sphere of the regular army surgeon serving at a post includes in addition obstetrics, gynecology and diseases of children. Every military surgeon must be an expert in physical diag-

Ambulance train on the way to the hospital ship *Relief* in the harbor of Ponce.

the regular army; without it he is not permitted to pass the medical examination. Statistics show that a large percentage of the candidates are dropped at this stage of the examination. This is a reflection on the system of medical education which continues to prevail in our country. About the only evidence of proficiency the National Guard surgeon in most of our States is required to show is his diploma. It makes but little difference when the diploma was obtained. Evidences of a satisfactory preliminary education are not required. In consequence of such an easy entrance into the medical service of our State troops, many of the men who receive commissions are illiterate. By hard post-graduate work they often become good physicians, but they seldom if ever make up for the early defects of their education, which seriously interfere with a successful military career. Is it to be wondered at that when such shortcomings are discovered by their colleagues and officers of the line, they do not command the respect their commissions, should entitle them to? The reports made out by such men speak for themselves, and appear as black stains upon the department they rep-

Litter work in the court of the Spanish military hospital in Ponce.

resentation and examination of the eye and ear. He must know something about dentistry, he must know how to extract teeth and how to put in a temporary filling in a carious tooth that can be saved. He must be familiar with neurology, the use and application of electricity as a diagnostic and therapeutic resource. In camp and field he is limited to his own resources in the diagnosis and treatment of all kinds of injuries and diseases. He must therefore be well equipped with a thorough knowledge of everything pertaining to surgery and medicine, and is often called upon to represent the different specialties. No amount of preliminary and professional education will make the military surgeon an efficient officer unless he is possessed of an inborn aptitude for the profession. He must be able to apply and make use of his knowledge. Many men of great learning never become successful practitioners. Their store of knowledge fails them when they come to apply it. The military surgeon in camp and field must be a man of quick perception. He must be able to recognize malingering as well as disease. In an emergency he must be in readiness to act intelligently at a moment's notice. Hesitation is

dangerous both to the patient and the reputation and good standing of the surgeon. Indecision creates mistrust, procrastination disaster. Quick decision and prompt action are the essential prerequisites of successful emergency work. Successful action, however, must be preceded by thoughtful, systematic preparation. The most successful surgeon is the one who adopts and follows the watchword, *semper paratus*. He should never be caught napping. Careful preparation makes prompt action possible. The successful surgeon makes his plans ahead and supplies himself with the necessary outfit, medicine, dressing materials and instruments before the emergency arises, and when it does so he is fully prepared to meet it. A lack of forethought and systematic preparation accounts for many shortcomings of medical officers in the field and camp, with the necessary evil consequences for those entrusted to their care.

Military spirit.—Any one who enters the medical service of the army as a life avocation will be disappointed unless he does so imbued with a proper military spirit. The military surgeon must be a military man and an integral part of the army, if he wants to

must resort to measures that will enforce it. The lack of military dignity on part of the medical staff is due largely to a lack of the proper military spirit in the members which compose it, and to too great a familiarity between the surgeons and the officers and men. The correction of these evils can not be undertaken too soon, and when accomplished will add much to the dignity, influence and efficiency of the medical department of the army and State troops.

The medical officer who has enjoyed the advantages of an early military training in a military academy or the national guard, is the one best qualified to enforce military rules and assert the dignity of his position.

Punctuality.—The busiest men have always the most time to perform a duty or to meet an engagement at the appointed time. This rule holds good in all walks of life. The drones are always behind. In military life punctuality means everything and from this exaction the medical officer should never be excluded except for special and well founded reasons. In the regular army there is a way of disciplining the medical as well as other officers in coming to time in

Court of the Spanish military hospital in Ponce.

do justice to his calling and the department he represents. I fear it is a lack of the proper military spirit in some of the medical officers in the regular army that is responsible for a well recognizable cleft between them and the officers of the line and field. If this is true in the regular army, it is only too obvious in the National Guard. The rank of the medical officers and their standing in military and social circles suffer when they are regarded and treated as an ordinary doctor. The West Point graduate, educated at the expense of the government, too often forgets that it takes more hard work and a longer time to make a good doctor than an officer. The officers of the National Guard, holding commission by the grace of their governor, do not realize sufficiently that their military surgeons have spent a small fortune and five years in acquiring a knowledge of their profession. They seem to forget, or at any rate often ignore, that when they go into camp or in the field they do so at a great personal and pecuniary sacrifice. Their absence from home, even for a short time, may cause a break in their practice difficult to repair. The medical officer is entitled to recognition as a military man, and if this is not accorded to him voluntarily, he

Transfer of patients to the lifeboat in the harbor of Ponce.

the performance of definite duties and in making out the reports. My long experience in the National Guard service has taught me, occasionally in a painful way, that the surgeons are often entirely oblivious to the matter of time, especially in the matter of making out and transmitting the regimental reports. It is the men who put off for tomorrow what should be done today, and who meet their engagements at one o'clock or thereafter instead of twelve, that render the life of their superior officers one of misery and full of disappointments. The men that accomplish the most are always ready and on time. The medical officers must be made to understand that a due regard for punctuality in performing their duties, in meeting appointments and in mapping out and forwarding reports is one of the most essential features of a successful military career.

Courage.—It is still the general belief that, in times of war the military surgeon is exposed to less danger than the soldiers and officers in command. That this is not so is shown by the statistics of all wars. Although the position of the military surgeon is behind the fighting line, he is usually near enough to the enemy when serving in the front to be

reached by stray bullets and bursting shells. The number of surgeons killed and wounded in the performance of their duty in rendering first aid is by no means small in any war of magnitude. In active warfare, however, the greatest danger to the surgeons is to be found in their constant exposure to contagious and infectious diseases, which follow large armies in all climates and during all seasons of the year. To enter a yellow fever camp, to my mind, calls for more courage than to lead and command the troops in the battlefield. Disease always claims more victims than bullets, and this is especially true of the present war with Spain. The nation worships the heroism of those who fell before Santiago, but much less is said of the vastly greater number stricken down by disease, and who have lost their lives from disease, often after prolonged and intense suffering. To the credit of the medical officers of this and other wars it must be said that they showed no fear, either in facing the enemy or what is vastly worse—disease. When yellow fever made its appearance among the troops around Santiago, every man remained at his post and faced the danger without flinching. Men from the North who had never seen the disease accepted the detail for duty in the fever hospitals without a word of complaint. The medical officer must be endowed with more than ordinary courage to face the many dangers that surround him on all sides during every campaign. Patriotism begets heroism and I make a well-founded claim for both for the medical profession represented in the army.

Personal habits.—The old adage that "It is easier to preach than to practice," is a familiar one and should be made to apply with the same force to doctors as preachers. The first and most important duty of the military surgeon is to prevent disease. This can often be done more effectively by example than by precept. The military surgeon must guard the camp against disease. He is looked upon and must be regarded by those under his care as the one above all others who can give them advice in matters pertaining to their health. He is expected to do this by example as well as precept. He must become a permanent object lesson in inculcating the importance of cleanliness in person and in dress. His tent should be the cleanest and most orderly in camp. Temperance in eating and drinking can be taught more successfully by action than by words. A military surgeon under the influence of liquor will do more harm in encouraging the vice of intemperance than can be undone by weeks of lecturing. Profanity is prevalent in every camp and while it is not the duty of the surgeon to supplant the chaplain in suppressing it, it should receive no encouragement by his example. In his conduct toward the men the surgeon should be firm and dignified, yet kind and sympathetic, especially to those in need of his professional services. An impetuous nature and an irritable temper create a rebellious spirit, which it is difficult to control by the most energetic measures. Proper questions should be answered willingly and with sufficient clearness and adequate length to furnish the desired information, and not gruffly and snappishly, as is occasionally done without any reason or provocation. Overwork and a disordered digestion are poor excuses for treating a subordinate in an undignified, ungentlemanly manner. The military surgeon must be known in camp as a gentleman, not only by the officers but by every man under his

charge, if he expects to be respected and to do justice to his high calling and responsible position.

The military surgeon in war.—The true qualities of the military surgeon are crystallized and best known during an active campaign. It is in war that his ready resources will come to the surface and will be subjected to the severest tests. It is in battle and during the prevalence of devastating diseases that his moral courage and physical endurance will be most severely tried. It is under such circumstances that the troops will look to him most confidently as their protector and nearest and dearest friend. It is not in peace but in war that the bond of true comradeship becomes tighter and tighter between him and the officers and men. It is on the march, in camp, and on the battlefield that the important function of the military surgeon receives the recognition to which it is entitled. It is the wounded and the sick in a strange land that look to him for help and restoration to health. It is the surgeon who so often receives the last message of the dying.

The first and most important duty of the military surgeon during active warfare is to prevent disease and unnecessary suffering by giving early advice and resorting to timely precautions. The location of camps, policing of the same, the water-supply, food and clothing are subjects which must receive his early and earnest attention. In this work he should receive the hearty co-operation of the officers in command and if this is not the case he has the moral and military authority to demand it. It was not the medical department, but the arrogance or stupidity of the commanding general of the invading army that is responsible for the extensive outbreak of yellow fever during the Cuban campaign. This experience is sufficient to teach commanding generals that it is unsafe in the future to follow such an example, as an imprudence of this kind, giving rise to inexcusable slaughter and indescribable suffering, will meet with universal indignation. The military surgeon is in reality the family physician of the men placed under his charge. He attends to the little ailments with the same care as though he had been sent for by a wealthy family and expected a handsome fee. To be successful in the treatment of disease he resorts to the simplest medication. Complicated prescriptions are dangerous and absolutely out of question in military practice. The tablets containing drugs in the most concentrated form are a great blessing to field practice and should be relied upon almost exclusively in the treatment of disease. The remedies needed are few, and if well chosen and applied will answer all indications. A liberal supply of quinin, opium, calomel, strychnia, camphor, iron, arsenic, bicarbonate of soda and bromid of potassium will leave but little to be desired. Turpentine, castor oil, alcohol and the anesthetics are about the only fluid medicines the military surgeon has any use for. The breakage and waste in dispensing medicines in bottles are inexcusable in modern field work. Fancy drugs and preparations should not be tolerated. In the practice of surgery the military surgeon who wishes to attain the maximum success must be conservative. Strict asepsis and conservatism are the two things which are destined to make military surgery successful. Every surgeon must have special training in emergency work. He must be perfectly familiar with the indications and technique of every operation which may become necessary in the field. He seldom will have an opportunity to cut

for stone, extract a cataract, remove an ovarian tumor or operate for other benign and malignant growths, but he must know how to treat a compound fracture in the most modern and approved manner; he must be skillful in the treatment of wounds of all kinds, and he must be a master in performing an amputation and in ligating arteries in any part of the body. He must learn to perform all emergency operations with the simplest facilities and fewest instruments possible, in order to adapt himself in time to the exigencies of war. The surgeon who can extemporize an operating table in the field and who can secure asepsis with the use of the camp kettle, soft soap and carbolic acid or sublimate and who can perform the most difficult operations with the simplest and fewest instruments, with little or no assistance, is the one who will accomplish the most and who will obtain the best results in the field.

Ponce, Porto Rico, Aug. 8, 1898.

TREATMENT OF RETRODISPLACEMENTS OF THE UTERUS BY SHORTENING THE ROUND LIGAMENTS PER VAGINAM.

Presented to the Section on Obstetrics and Diseases of Women, at the
Forty-ninth Annual Meeting of the American Medical Association,
held at Denver, Colo., June 7-10, 1898.

BY J. RIDDLE GOFFE, M.D.

PROFESSOR OF GYNECOLOGY NEW YORK POLYCLINIC; VISITING
GYNECOLOGIST TO CHARITY HOSPITAL, ETC.
NEW YORK, N. Y.

Dr. Howard A. Kelly, at the recent meeting of the American Gynecological Society at Boston, announced in a discussion that he had collected a list of forty-five different operations that had been suggested for the relief of retrodisplacements of the uterus. Accepting this statement as true, what more suggestive fact could we have of the importance in which this affection is regarded by the profession, or of the assiduity with which the profession has devoted itself to its relief?

Much has been learned regarding the dynamics of the female pelvis, but much still remains to be discovered. Plates representing sagittal sections of the female pelvis taken from frozen sections have been transmitted from one generation of text-books to another, and the errors therein depicted have likewise been transmitted from one generation of medical men to another. The section of a frozen pelvis represents the relation of the parts in that individual only, and in all probability does not correctly represent the relation of these parts during life. It is a recognized fact that the uterus rests in a position of unstable equilibrium, varying in its position with every movement of the body and with every respiration, so that the average position of the uterus as obtained after an examination of many living women is the only way of reaching a conclusion as to even a proximal ideal position. A great advance was therefore made in definite knowledge upon this subject when an investigation was instituted for the purpose of more positive information by examining *living* women, while standing in an erect posture. By this method of investigation it has been reliably determined that when a woman is upon her feet, and that is the position in which all great effort is made and the forces brought into play which tend to retain or remove the uterus from its normal position—it has thus been determined

that when the body is in an upright posture the uterus normally rests upon its anterior face and is suspended in a cradle or sling of tissue reaching from the symphysis pubis to the sacrum, known as the vesico-uterine ligaments in front, and the utero-sacral ligaments behind. The uterus is steadied in this position by the broad ligaments, reaching from either side of the pelvis to the uterus, and the round ligaments, which tend to restrain the uterus in its anteverted position, and indirectly to support the broad ligaments.

Accepting, then, the broad principle that Nature is consistent in her work, and applies to the uterus the same mechanical principle that she utilizes in supporting all other organs of the human body, we must conclude that the uterus is supported by ligaments.

The uterus itself is not an organ of any great weight, and requires only delicate structures to retain it in its proper location in the pelvis. It is, however, subjected to intra-abdominal pressure which must be counteracted. Let us see, then, how this is accomplished. Resting as it does, upon its anterior surface, or in other words, having its anterior face looking downward, it receives the intra-abdominal pressure expended in the pelvis upon its posterior surface. If then the sling of tissue which sustains the cervix high in the hollow of the sacrum is sufficiently strong to retain it in that position, all intra-abdominal forces impinging upon the uterus tend to force the fundus still farther to the front, and so help to maintain its normal anteverted position. We must therefore look to the tissue between the cervix and the sacrum, viz., the utero-sacral ligaments, as the chief factor in maintaining the anteverted position of this organ. If for any reason these ligaments become over-stretched or relaxed, so that they lose their contractile powers, the entire uterus settles in the pelvis, and the cervix swings correspondingly to the front, thus preventing the resultant of intra-abdominal forces from carrying the fundus to the front until this stretching process has reached such an extent as to actually permit them to impinge upon the anterior segment of the uterus and eventually carry it into a position of retroversion. In this process all of the ligaments gradually become relaxed as the strain is put upon them until not only one or two, but all of them lose their tone, and the uterus becomes hopelessly displaced. Such, to my mind, is the rational explanation of the etiology of this affection. In a normal unimpregnated uterus the round ligaments alone may be relaxed to any degree you choose and the uterus will still remain in place; the same thing may be said of the broad ligaments; but once you relax permanently the utero-sacral ligaments, and you at once set in motion the process that eventuates in retroposition.

The most frequent cause of this relaxation is undoubtedly the absence of prompt and efficient involution following parturition. Next in order of causation, I place prolapsed and diseased appendages, which, resting upon these structures and becoming adherent to them, so interfere with their nutrition that they eventually relax and allow the cervix to swing to the front. Another and not infrequent cause is the presence of a fibroid tumor located near the uterine insertion of the utero-sacral ligaments.

The condition of retroversion and retroflexion is not confined however to married women. In single women, especially in cases of congenital retrodisplacements, the etiologic factor is also to be found in the cradle

or sling of tissue reaching from the symphysis pubis to the sacrum, but instead of being posterior to the cervix, the cause of displacement is to be found in the vesico-uterine ligaments, and more especially in the manner of their insertion into the uterine tissue. Reynolds of Boston, following Foster and Ranney, and Hart and Barber, has called attention to the fact that the method of attachment of the tissues about the cervix is an important element in retaining the uterus in its normal position. For example, the anterior position is maintained by the tissues in front of the cervix being inserted into it at a higher level than that at which the tissues posterior to the cervix are attached. If, for any reason, by an anomalous anatomic arrangement, the tissue in front is inserted at a lower level than the tissue behind, the natural pull of these ligaments tends to throw the fundus backward. This condition is exactly the one that is so often found in congenital displacements, and in fact in all retropositions of the uterus as found in unmarried women, and probably the majority of these are congenital—that is the cervix being in the axis of the vagina and the anterior wall extremely short, showing that the utero-vesical ligaments are inserted very low down. This principle has been taken advantage of by Reynolds of Boston, in an operation for the relief of this condition in virgins, in which he simply detaches utero-vesical ligaments from their low insertion and stitches them to the anterior face of the uterus at a little higher level. He reports a number of cases in which he has applied this treatment successfully. This certainly seems a most rational procedure.

In accordance with the dynamics as previously explained, however, the most rational relief of retrodisplacements is to be found in some operation which will shorten or restore to their normal condition the utero-sacral ligaments. An effort has been made to accomplish this by some German operator and also by one or two surgeons, in our own country, but the difficulties of reaching these structures, either through the abdominal wall or per vaginam, are so great that thus far no satisfactory results have been obtained. It is my belief, however, that in shortening these ligaments is to be found the proper method of treating these persistent cases. Next to the utero-sacral ligaments the most rational structures to be utilized in an operation for the relief of this condition are the round ligaments. While the functions of the round ligaments, are to direct and limit the excursions of the fundus from its normal position, rather than to sustain the weight of the organ and resist the pressure upon it, nevertheless experience has shown that they are quite equal to the latter offices, at any rate for a sufficient length of time to allow the utero-sacral ligaments to regain their function.

Today by far the most popular operation for the cure of retroversion, and the one most frequently employed by operators throughout the country, is either the original or the modified Alexander operation. The objections to Alexander's operation, however, are many: 1. It has a limited field of application, being restricted absolutely to cases in which the uterus is perfectly movable and the appendages free from disease. Such cases in my experience constitute but a very small proportion of those requiring relief. 2. The round ligaments can not always be found at the external ring. In this connection it may be noted that a number of cases have been reported in which an anomalous insertion, either into the fascia about the internal

ring or at the outer border of Poupart's ligaments has been found. Moreover, in many instances the ligament is so frail in this part of its course, that it does not withstand the strain necessary to draw it out of its bed and breaks in the procedure. 3. The operation necessitates two incisions and two objectionable scars in the abdominal wall. 4. The operation in the hands of every operator experienced in this procedure is followed by hernia in a certain percentage of cases.

In order to extend the field of application of the Alexander operation so that it might include cases of retroversion with adhesion and with diseased appendages, Drs. Wylie and Dudley of New York, and Dr. Mann of Buffalo, have suggested and put into practice a method of shortening the round ligaments within the pelvis through an incision in the abdominal wall. The procedure in the hands of these three operators differs only in the manner in which the ligaments are doubled back upon themselves. The results, however, have been satisfactory, and the operation is still practiced by them all. The objection to it, however, is that it necessitates a laparotomy with all its attendant discomforts and possible hernia, and in simple, uncomplicated cases is altogether too serious a procedure for so simple a condition. Other operators, in their endeavor to avoid laparotomy, have opened Douglas's pouch through the vagina; broken up the adhesions, thus setting the ovaries and appendages free; and then shortened the round ligaments at the external ring.

As this operation which I am doing has to deal with the round ligaments, I have expended most of my time in discussing that structure as the natural support, without entering upon the relative merits of abdominal fixation, which I believe has a certain field of application, although a limited one.

With the work of these operators in mind the idea naturally suggested itself of opening the peritoneal cavity through the anterior vaginal fornix, breaking up the adhesions, restoring the uterus to its normal position and shortening the round ligaments through the one incision. This has been found a perfectly feasible procedure, and has met with such success at my hands that I have ventured to urge its adoption in all cases of retro-position of the uterus, whether simple or complicated.

The technique of the operation is as follows: After rendering the parts thoroughly aseptic, curetting the uterus and packing it with iodoform gauze, the cervix is seized by a vulsellum forcep and dragged down to the vulva. A transverse incision is made just in front of the cervix through the vaginal wall, as in the procedure for vaginal hysterectomy. The bladder is then stripped from the anterior face of the uterus and the finger pushed through into the peritoneal cavity. Grasping the edge of this transverse incision near its middle point by two artery clamps, the anterior vaginal wall is put upon the stretch and the longitudinal incision is made in the anterior wall throughout its whole extent. The bladder is then dissected off the vagina for a distance of half an inch either side of this longitudinal incision. The purpose of the latter incision and the separation of the bladder is to secure sufficient room through which to work. The dissection is done almost entirely with the handle of the scalpel and the finger, and the hemorrhage is inconsiderable.

The finger is now passed over the uterus and by

careful but persistent efforts the adhesions are broken up, both those to the uterus and those to the appendages. By hooking the index finger over the broad ligament near one cornua of the uterus, the latter organ is gradually delivered into the vagina. The ovaries and tubes are readily drawn down afterward, where, in full view and of easy access, they can be treated in whatever way may be indicated. The diseased portions of the ovaries may be resected, portions of the Fallopian tubes removed, or the appendages of one side may be removed and conservative work done upon the other side, or if the appendages of both sides are found hopelessly diseased, they and the uterus can be easily removed.

The proximity of the horn of the uterus to the vulva enables a ligature to be applied about the appendages and as near to the fundus as may be desired. After the appendages have been cared for, the round ligament, first of one side and then of the other, is caught by an artery clamp from one to one and a half inches from the horn of the uterus and dragged down in the form of a letter "U." In this position a fine braided silk ligature is passed through the ligament at as remote a distance from the forceps on the outer side as will allow approximation when it is passed through the ligament near to the horn of the uterus. It is then tied, thus shortening the round ligament to an extent equal to the length of tissue taken up in the loop. Two other smaller sutures are passed between this one and the forceps, and finally a third one, catching the tip of the loop and attaching it to the anterior face of the uterus just at the origin of the round ligament. The horn of the uterus thus treated is allowed to resume its position in the pelvis, the other horn of the uterus drawn down and the round ligament of that side treated as in the first instance. The uterus is then allowed to take its normal position of anteversion, and the bladder tissue that was dissected from the uterus is adjusted in its original position. The tissues are not sutured to the uterus, but a running catgut suture is applied through the extent of the longitudinal incision. The vagina is then comfortably packed with iodoform gauze and the operation is completed. In cases of congenital retroversion not only are the round ligaments shortened by this operation, but uterine insertion of the utero-vesical ligaments is carried up on the anterior face of the uterus and the abnormal anatomic arrangement previously described is thus remedied.

The commendable feature about this operation is its wide application. Simple retroversion of the uterus can be relieved by the application of a properly fitting pessary, and it is a question whether the condition demands the application of any surgical procedure beyond that. The circumstances of the individual case, however, must determine action in that direction. The chief point of attention is the complications attending this condition. Through the anterior vaginal wall all complications can be readily dealt with; from the simple removal of diseased appendages throughout the whole range of conservative procedures, and even to the extent of myomectomy for small fibroids and ovarian cysts of all kinds. During the past winter I have operated upon cases of retroversion with fixation, complicated by simple cysts of the ovary, by purulent cysts of the ovary, by pyosalpinx, and in one instance by a dermoid cyst containing about a quart of material.

Now as to results. The total number of cases sub-

mitted to this operation is thirty-one. The first operation was done in March, 1896, and the last done in May, 1898. In all my cases of simple retroversion treated in this way the results have been entirely satisfactory, not only in the anatomic cure, but also in the complete removal of all symptoms. Of these cases there have been six. I have had one case complicated by a dermoid cyst and five cases complicated by adhesion, club-shaped Fallopian tubes and cystic ovaries. In all these cases the ovary has been resected and the Fallopian tube amputated. In all the other cases the appendages of one side have been completely removed for destructive diseases of those organs, and in about one-half of them conservative work has also been required upon the remaining appendages. Of these cases, one patient from whom the appendages of one side were removed became pregnant shortly after the operation and was delivered of a healthy child in September, 1897, after a period of five years' sterility. This patient has been examined by me since and the uterus found freely movable and in perfect position.

A second patient, in whom conservative work was done upon the appendages of one side, the appendages of the other side being healthy, after a period of four years' sterility and intense suffering, became pregnant shortly after the operation, and since my arrival in Denver I have learned through my assistant that she has been delivered of a child weighing nine pounds, and that she has passed through this gestation with greater comfort than any of the three previous ones.

A third patient is now pregnant five months. In this case the appendages of one side were removed and the round ligaments shortened as usual. She reports no unusual symptoms during her gestation up to this stage.

As to absolute and partial failures. After having done the operation a number of times, it occurred to me that perhaps it would be an improvement upon the usual method of shortening the ligaments to free the ligament from its bed, double it upon itself and then allow it to retract beneath the peritoneum. To accomplish this an incision was made through the anterior face of the broad ligament just over the round ligament, and an aneurysm needle passed underneath the round ligament and slid back and forth to free the ligament from its bed. The ligament was then drawn out, doubled upon itself and stitched, and allowed to retract beneath the peritoneum.

In the first case this maneuver was attended by some hemorrhage, but not enough to deter me from applying it a second time. In the second case, however, a hemorrhage occurred, not alarming in its extent, but most persistent in its character. This hemorrhage came from the blood vessels accompanying the round ligament in its course. After trying various methods of controlling the hemorrhage without destroying my work, I despaired of success in this way and concluded it was best for the safety of the patient to at once remove the uterus, which I did. That was the only case in which any hemorrhage, even of an annoying character, has attended the work. It was due to the modification which I adopted and which was promptly abandoned.

In the cases in which it became necessary to remove the appendages of one side, I endeavored to economize time by drawing up a loop of the round ligament of that side and including it in the common ligature. In accordance with my custom, I used

catgut ligature, and have had the mortification of discovering that in two of these cases, two months after the operation, the ligament of that side has given way and the uterus has swung around to the opposite side in a position of partial retroversion. Both these cases, however, had suffered from persistent irreducible retroversion, and since this accident have both been completely relieved by the insertion of a retroversion pessary. Hereafter I have decided not to include the round ligament in the ligature applied to the appendages, but to go through with the routine process of shortening the round ligament upon that side as well as upon the other. By doing so I believe that the accident referred to can be avoided. All of the other cases have been completely relieved of symptoms, and when last seen were anatomically cured.

The more experience I have with the operation the more satisfactory it becomes. In not one of the cases has there occurred a single complication in the process of convalescence. There has been no shock, no temperature. The after-treatment is extremely simple. The vaginal and uterine gauze is removed upon the fourth day, and thereafter no further treatment is required except a daily vaginal douche.

DISCUSSION.

Dr. ALBERT GOLDSPOHN, Chicago—I congratulate the doctor on the commendable work he has been doing in this direction. The efforts of attending to the indications for pathologic conditions in the female pelvis through the vagina, originated, we may say, with Duhrssen, Mackenrodt, Aug. Martin, of Berlin and others, and are somewhat repeated in the operation described here. I have done the same operation about a dozen times without difficulty. I consider it a feasible operation, and certainly one to be esteemed above those other unsurgical procedures which need to be relegated to the past. I mean ventrofixation, vaginofixation and ventrosuspension. These procedures are repugnant theoretically and practically to surgical instinct, and I am surprised that people of so much scientific common sense as the Germans should be the fathers of these procedures. We need such loans from the domain of pathology, for some extreme cases of prolapse, for instance. I will not totally condemn any one thing that was ever done by rational physicians with repeated success.

Doctor Goffe is not entirely correct in placing the symphysis pubis at a lower level than the tip of the coccyx in the standing woman. That is an error. The dynamics with relation to the genital organs as stated by him are in the main correct. But intra-abdominal pressure must be carefully defined if we would escape objections from our opponents in this question. The reason why I have not more frequently done vaginal shortening of the round ligaments, or vaginal fixation of the round ligaments, as now done chiefly by Wertheim, of Vienna, is because we need to adopt a different plan in our indications for operating for displacements of the uterus and its appendages. The reason why so many cases are not wholly well that have been properly treated as far as the operation went, in restoring the uterus alone to normal position, is because the same treatment was not extended to the adnexæ also. The majority of retroversions of the uterus have such conditions of the adnexæ that they require conservative operations as the Doctor has suggested. But the reason the ovaries became so diseased in a large proportion of cases is because they were previously displaced; they were away from the lateral normal location against the pelvic wall; they had migrated toward the median line of the pelvis and to a far lower plane; where they were subjected to traumatism between the uterus and the rectum, as well as to the evils of venous hyperemia. The uterus when retroverted is crowded on to the displaced ovary by abdominal pressure. If, then, the displacement led to the disease in the ovary, we need to correct not merely its condition, but above all, its position also. We must do something with the displaced ovary after we have resected it, secure it in normal position. This requires good access to the lateral walls of the true pelvis, which is not at all obtainable by any vaginal incision. For this can only intensify the ovarian displacement, but not correct it. For that cardinal reason, I can not make use of the vagina anywhere near as frequently as I would. The principle the Doctor states of the sacro-uterine ligament main-

taining the equipoise of the uterus in normal anteversion is correct, although the numerical proportion of inefficiency of the sacro uterine ligaments, as stated by him, is too great.

Dr. HENRY P. NEWMAN, Chicago—I was highly pleased with the paper and with the stand taken by Dr. Goffe. Ten or twelve years ago, when this work was advanced, particularly the round ligament operation, we had very few that would sustain us in our work, many members of the profession believing it to be visionary and work that would only last for a short time. At the present time it is highly commented upon all over the country. The objections, however, that are met with even today that deter many physicians from adopting the round ligament operation are, I believe, simply faults in technique. By making the primary incision over the external ring, thereby finding a ligament that is well developed, when it is drawn out it is the abdominal portion of the round ligament. The abdominal portion of the round ligament is a different structure, is of different size, more stable and decidedly a better support than that of the inguinal canal portion of it. Moreover, the inguinal canal portion of the ligament when drawn on stays in the old operation; that is, by being stretched it is frequently attenuated, is reduced materially in size, and is not the intra-abdominal ligament at all. It does not accomplish much in bringing and holding the uterus forward, and consequently the operation is a failure. If the round ligament is drawn out on a line with the attachment of the uterus, you are sure of drawing out the part of the ligament which needs to be shortened, namely, the intra-abdominal portion. This much and other points in relation to operating upon the external ring are features that I brought out some ten years ago, and have adhered to with most satisfactory results, and those gynecologists who have followed this method of operating have been equally well satisfied. I do not think, as the Doctor stated, that the etiology of displacements of the uterus is confined to these two ligaments. I refer particularly to congenital cases so called, or cases that are really faulty at puberty. The uterus at birth in these cases is uniformly an infantile organ, but after puberty an arrest of development means under all circumstances a puerile condition of the organ. There may be a long cervix, and a fairly well developed fundus lying upon a conical cervix. This is a factor in producing displacements.

Dr. HOWARD A. KELLY, Baltimore—I naturally feel interested in this discussion, as I have operated a great many times for these conditions. I believe no surgical operation will restore *ad integrum* these tissues and the uterus where they were before. If this is not accomplished by plastic operations and rest preventing a tendency to descensus, then the question is one of the best surgical operations from a mechanical standpoint. I believe all these operations should be supplemented by restoration of the floor of the pelvis. I do not believe that the round ligaments support the uterus. They are always found kinked in abdominal operations and hence can not be supported. With the uterus retrodisplaced, the abdominal force increases the trouble, while if the uterus is anterior it increases the anterior displacement. A thread applied to the fundus holds it in this normal position and the pressure then falls upon the posterior surface. The floor should then be restored. I have operated through a one and a half inch incision over four hundred times, and only about 2 per cent. of the cases relapsed. About twenty of the women have become pregnant. All are doing well but one, and in her case agglutination occurred. Fixation is not the proper procedure for these cases; it is suspension that is required. None of the cases died. Severe pain has not been noted in any case. I do not include the fascia or muscle in my stitch, but only the peritoneum and subperitoneal tissue.

W. B. CRAIG, Denver—I would like to say a few words in support of the Alexander operation. I have had no experience with vaginal fixation, but have performed the Alexander operation in nearly a hundred cases. I have been looking for some of the accidents and dire consequences which I read of in the medical journals, and I am glad to say to you that I have been disappointed. I know of no case of hernia following any of my operations, and I kept track of the majority of my cases. No dire consequences have followed from infected ligatures, or cases of sepsis from any cause. In a body of this character these operations are purely technical. If we are attempting to instruct the general practitioner, who is rapidly becoming accustomed to surgical work, both special and general, then the matter takes on a different aspect. Any surgeon or student with a little preparation can do an Alexander operation with comparative safety; but it takes an expert to do a vaginal operation, especially of the nature of those described here this afternoon. Of course, the old method in the Alexander operation has been discarded. I do not believe the time will ever come when abdominal section will be

absolutely without mortality. This operation (the Alexander) has practically no mortality. In my series of cases I have had possibly one case of recurrence of displacement. Dr. Kelly struck the keynote when he said that anything that will hold the uterus forward for a short time until we get what is known as involution or reduction in the size of the organ will effect the purpose. It is much simpler to make an inch and a half incision in the groin than in the belly, as we do not have the risk of adhesions, of volvulus and other occurrences which occasionally follow the most careful abdominal operation.

S. C. GORDON, Portland, Maine.—There are two or three points in connection with Dr. Goffe's paper that I wish to touch upon. I doubt very much the proposition made by Dr. Goffe that the utero-sacral ligaments have much to do in supporting the uterus. It seems to me the broad ligaments have very much more to do with supporting the uterus than anything else. In relation to the support of a uterus which has a certain amount of descensus, it seems to me that we must have something at the top in one way or another to hold it forward. The only exception I would take to Dr. Kelly's method is that I would use catgut instead of silk, feeling sure then that I would have nothing which was going to act as an irritant and produce trouble afterward. After all, if union of the peritoneal surfaces is desired, it may be obtained by good catgut, and you have an absorbable material which is taken care of; so that between Dr. Kelly's operation and the operation for shortening the round ligaments, I should confine myself to those two, and should always do them through an abdominal opening. I am not much in favor of vaginal operations for remedying or treating these conditions. We can treat these conditions so much better through a small abdominal opening than by resorting to the long process described by Dr. Goffe. I do not like it, but Dr. Goffe does, I have no doubt. I do believe, however, that through a small abdominal opening we can get at things and do them much better; we can do conservative operation upon the ovaries and tubes and put them up where we want them. But it seems impossible to me when we resort to the vaginal operation. Then, again, no vaginal operation can be done without resulting more or less in the formation of scar tissue which may become a source of pain. So the point is this with me: Abdominal section with fixation or shortening the round ligaments by either the Dudley or Mann operation, Mann's preferably, fix the uterus forward a little while and the thing will take care of itself.

Dr. HENRY O. MARCY, Boston.—At one time I was very enthusiastic in regard to the Alexander operation. I was one of the first surgeons in this country to adopt it and have had considerable experience with it, and have utterly abandoned it. It is a popular operation with us in Boston; but as I have seen so many cases of hernia that have presented themselves to me after this operation, I am compelled to believe that it is the exceptional operation that we should do. It may be advisable to do it under certain conditions, but the surgeon must know the condition of the pelvic structures. We know that in the vast majority of cases there is something besides the mobility of the uterus with which the surgeon has to deal, and that something is an unknown factor unless we open the abdomen. For years I have adopted the method of opening the abdomen, as advocated by the last two speakers, determining the factors with which I had to deal, and instead of using silk, as I believe Dr. Kelly does, I use the animal suture on either side close to the cornu of the uterus, making double fixation. I believe Dr. Kelly puts one suture into the fundus and another a little posterior to it. There is considerable advantage in placing sutures on either side; it does well in my hands, and whatever means we resort to we should be careful as to the other factors, to-wit, the endometrium, the cervix, the perineal structures, and look after the circumferential factors as well as the one condition of malposition of the uterus proper.

Dr. CHARLES I. BONFIELD, Cincinnati.—In regard to the etiology of these cases, it seems to me Dr. Goffe has very much exaggerated the rôle the utero-sacral ligaments play in supporting the uterus. If any of you will take a case where the uterus is in its normal position, pull it down to the vulva, and take pains to introduce the finger into the vagina and feel where most of the traction is made, you will find it is not altogether in the posterior cul-de-sac.

Another point is the normal tone of the structures that hold all the abdominal organs in place. Most of you must have observed cases of slight ventral or inguinal hernia in which it was considered unnecessary to wear a truss; and yet when these patients became run down in health and the tissues became lax the hernia gave much more trouble. When their health was improved again their hernia practically disappeared. I have had cases that have gone on for five or six

years without a truss who had worn it for years. They become ill with pneumonia or typhoid fever, and again the truss has to be worn. This is a factor which should be considered in treating uterine displacements.

Dr. MILO B. WARD, Kansas City.—I can not see how it is possible for us to make such a bugbear of entering the abdomen and dissecting the vagina, bladder and uterus with perfect impunity. It seems to me, every case of retrodisplacement or of retroflexion can not depend upon the utero-sacral ligaments. A retroversion may do so, but certainly not a retroflexion. If you put your finger in the cul-de-sac of Douglas the uterus will fall back quickly if you do not keep it there. The utero-sacral ligaments have nothing to do with it. Every case of retroflexion is pathologic only when adherent by some condition of the appendages holding it there or a fibroid in that portion of the uterus lying next to the cul-de-sac. So we must do something with the appendages in all cases. That being true, we must go into the abdomen. I can not, I am sure, go into the vagina as the essayist can and bring forward adherent appendages by looping the finger over the fundus of the uterus, because I find in hysterectomy, while I have gotten the position before and behind me and have every opportunity to get in behind the uterus, I use a hook to bring it forward; I can not do it with my finger. If we operate through the abdomen, which we ought to do in nearly all cases, we can shorten the round ligaments as it is done in New York and other places, or as I have done it in my operations. I loop the round ligaments to the anterior aspect of the uterus thereby shortening them. This can be done in a minute or two with kangaroo tendon; it is perfectly safe, and holds the uterus a short time until the pubic bone becomes stiffened, and it remains as long as you want it. I do not believe the Alexander operation is applicable in these cases, because if we do the operation at all, we are doing it on a case that is not very pathologic, for the reason the uterus is movable, and pessaries will act as well as an operation and are certainly much safer.

Dr. WILLIAM H. HUMISTON, Cleveland, Ohio.—As I stated a year ago, I have not used the Alexander operation, for the reason that if we have disease of the adnexa the case can be cured without that operation. If you have a misplaced organ for a number of months or a year or more, if the diseased condition is continuous, there is a change in the tubes and ovaries, and by bringing the uterus forward, after having curetted the diseased mucosa and reduced the size of the uterus, it will remain in place if supported six or eight weeks by a pessary. The majority of cases of retrodisplacement of the uterus only exist for a short time and can be cured simply by placing the uterus well forward and supporting it for a few weeks with a pessary, then the pessary can be removed and the uterus will remain in place. If you have changes in the adnexa, then the uterus is liable to go backward again. Therefore, in the Alexander operation you have a movable uterus; you must have the appendages healthy or the mere shortening of the round ligaments is not going to relieve symptoms. If you have displacement with healthy adnexa, the Alexander operation is not indicated, and mild curetting and placing the uterus forward are sufficient. In cases where we have diseased adnexa, I open the abdomen for the purpose of examination. I anchor the uterus forward, and use kangaroo tendon with which to hold the uterus to the abdominal wall. I do not scarify. It will hold the uterus there a sufficient length of time for the adhesion to take place. It is elastic and it will relieve the case.

Dr. W. O. HENRY of Omaha.—I can hardly agree with the essayist regarding the anatomy that he gave either as to the position of the symphysis pubis when the patient is standing, or as to the importance of the attachments, both anterior and posterior.

In regard to the operation of Dr. Goffe, I should say it is a difficult one, and an unnecessary one as a rule. Personally, I prefer to open the abdominal cavity and attach the uterus after the manner recommended by Dr. Kelly, by the slender peritoneal attachment, and I think the remark he made should be emphasized, because I believe there are many cases in which bad results have occurred after ventrofixation. In such operations as ventrofixation, where the peritoneum is scarified, we get an absolutely immovable uterus. But when a silk ligature is introduced through the entire thickness of the abdominal wound, you get a strong enough peritoneal tissue to hold the uterus in place. Where there are no adhesions and the peritoneum is all right, where the uterus is not necessarily large, no operation is needed. In many cases the uterus can be replaced and patients cured of their trouble by the use of a suitable pessary. I believe in the use of the pessary in such cases; but where an operation is necessary I still believe in operating by the abdominal method. I open the abdomen,

attach the uterus by two ligatures to the abdominal wall. If you have two ligatures within each other you are likely to get a dropping into a little nook a piece of omentum or bowel, strangulation taking place, and necessarily you will have to reopen the abdomen. A single ligature for suspending the uterus will generally answer in the majority of cases.

Dr. GEORGE J. ENGLEMAN, Boston.—The subject under discussion is a very broad one, and we all have our preferences. My own preference has been to attempt to restore normal conditions as far as possible, and not to replace one fixation by another, and, of course, fixations are now largely given up, likewise suspension. We must all yield to Dr. Kelly's success and the number of his cases. From close observation extending over quite a long time we must all admit that fixation is injurious unless it is resorted to in older women, where possibly the appendages have been removed and prolapse has occurred. I have seen a number of cases in which the delicate ligament has been stretched four or five inches or more, and yet it did not accomplish the object. If the good is accomplished in a given time, say in two or three weeks, I have no doubt the ligament holds. But frequently it is elongated more and more, and unless the normal conditions are restored, the operations are failures. I have preferred the shortening of the round ligaments with the restoration of other co-existing conditions. It has appeared to me that if we repair an old door we must repair the hinges, not nail it down either open or closed, but restore it as far as possible to normal conditions, and for that reason I prefer the shortening of the round ligaments through an abdominal incision in order to deal with the appendages, which in so many cases are at fault.

Dr. JAMES H. ETHERIDGE, Chicago—I have finally settled down for the past three or four years to abdominal fixation. Personally, I think there is very little difficulty in doing an operation through an inch or an inch and a half incision. As to ventrofixation, I have done many operations of this kind with only one abdominal suture. I suture through and through the abdominal wall, and one intra-abdominal suture is all I generally use in doing this operation. I have observed throughout this discussion that but very little allusion has been made to Dr. Goffe's paper. I am very glad to have heard Dr. Goffe's paper, because it is something new, and I want to hear what he will have to say three or four years from now. I still think I shall continue to do the abdominal fixation operation.

I am very much impressed with Dr. Ferguson's idea of suspending the uterus in this way. I cannot but believe that something will occur in loosening the stumps around the ligament, and they will slip back into the abdomen, one side or another. He says that is the fault of the operator or in the technique of our operations. If that occurs, he is hopelessly in the minority in the way of getting a reasonable expectation of good results from it.

Dr. JOSEPH PRICE, Philadelphia—In regard to the precise position of the ligature in these operations by Dr. Kelly, it has been disputed thrice or more by good men practicing the operation, each criticising one another's technique. One inserts the suture at the fundus or posterior to it, and the other a little more anterior. Thus, a paper was read by Dr. Ashton, one by Dr. Penrose, and I think, a third by Dr. Noble, each differing in the mathematical degree of position of the ligature.

Dr. JAMES H. ETHERIDGE, Chicago—I understand Dr. Kelly uses silk, and Dr. Gordon catgut. I have always used silkworm gut, leaving it in three weeks, taking out the abdominal stitches at the end of eight or ten days, and leaving the through-and-through silkworm gut stitches in three weeks. From past experience I have had in digging out silk material and other things from sinuses, I have gradually given up the idea of leaving a fixed suture in the uterus.

Dr. C. E. RUTH, Keokuk, Iowa—I have had considerable experience and some disappointments in trying to relieve uterine displacements. I think a pessary has its place in suitable cases. Had I known what the condition of the uterine adnexa was, I am quite sure I could not so well deal with the adnexa through the incision which Dr. Goffe makes as I could through an abdominal incision. I have done quite a number of ventrofixations that were very unsatisfactory, so far as relief from the symptoms was concerned for which the operation was done, and I have practically abandoned the operation for a year and a half, not believing that it should never be done, but I have not found a case in that time in which I thought the operation was indicated. I have since done it a few times, but I very much dislike to substitute one pathologic position for another. I am very slow indeed to believe that all cases of uterine retroversion and flexion are pathologic and demand treatment. I believe we will better subserve the interests of

our patients and own reputations if we make a small abdominal incision, and be certain as to the existence of a pathologic condition of the uterine adnexa. As to leaving unabsorbable materials in the abdominal cavity, I am less and less in favor of it as the years go by.

Dr. JOSEPH EASTMAN, Indianapolis—There is one point that was touched upon by the last speaker and Dr. Etheridge with reference to leaving material, such as sutures, which is not absorbed, and which I think is important. Silk, for example. Recently Dr. Tait has abandoned using anything else but silk. For a number of years I have boiled my silk, and then added quite a strong solution of carbolic acid to it. I have no trouble in digging out silk, and I think Mr. Tait resorts to a similar method. I do not think we should abandon silk altogether in our intra-abdominal work.
